HYLA ANDINA (NCN). **DIET**. Diet records for *H. andina* include insects (principally Diptera) and other small arthropods (Basso 1990. Monog. Assoc. Herpetol. Argentina 1:1–71). On 14 March 1998, we collected seven small adult *Hyla andina* under rocks along the Río Toro, 0.1 km E of the Ing. Maury Gendarmaria check point, Ruta Nacional 51, Departamento Rosario de Lerma, Provincia Salta, Argentina (24°41'15.0"S; 65°46'01.7"W; 2469 m elev.). The frogs were kept overnight in a ventilated, plastic 2-L container with 2 cm of water and maintained at 15–20°C. The following afternoon we found, at the bottom of the container, feces containing the remains (partial carapace, one chela, and one leg) of the small decapod, *Aegla* (probably *A. jujuyana*; Lopretto and Tell [eds.] 1995. Ecosistemas de Aguas Continentales, Tomo III, Ediciones Sur, La Plata, Argentina; Morrone 1996. Biogeographica 72:113–119). We thank M. Halloy for assistance in the field and M. Archangelsky for access to literature and for help in identification of the crabs.

HYLA BIOBEBA (NCN). **PREDATION.** Various species of mammals are predators of anurans (Duellman and Trueb 1986. Biology of Amphibians. Mc Graw-Hill, New York. 670 pp.). The consumption of frogs appears to be relatively widespread in marmosets (Digby and Barreto 1998. Neotropical Primates 6[4]:124–126; Passamani and Rylands 2000. Primates 41[1]:27–38). Herein, we report the first case of predation by the marmoset *Callithrix penicillata* on a neotropical treefrog, *Hyla biobeba*.

In July 2001 a subadult male *C. penicillata* was observed preying on an individual *H. biobeba* in a formation of cerrado, at Instituto do Trópico Subúmido – Campus II of the Universidade Católica de Goiás, Goiânia, state of Goiás, Brazil. The marmoset was observed at a height of ca. 2 m. While holding the treefrog by its trunk, the marmoset pulled off its head with strong bites. After eating the head, the marmoset subsequently ate the forelimbs and the abdomen, with nothing remaining of the treefrog.

While the marmoset was feeding, another juvenile *C. penicillata* approached, crying for food sharing, but the attempt failed. On two other occasions, *C. penicillata* was seen preying upon treefrogs at the same locality, although these frogs were not identified.

We thank the staff of Instituto do Trópico Subúmido – Universidade Católica de Goiás for allowing us access to the field station, R. P. Bastos for comments on the manuscript, R. F. Juliano for help on the English version, and CAPES for financial support.

Submitted by **GUSTAVO CANALE** and **RODRIGO LINGNAU**, Departamento de Biologia Geral, Instituto de Ciências Biológicas, Universidade Federal de Goiás, 74001-970, Goiânia, Goiás, Brazil; e-mail (GC): gustavocanale@hotmail.com.

HYLA CINEREA (Green Tree Frog). **REPRODUCTION**. In south Louisiana, *Hyla cinerea* breeds from May to September and is considered a prolonged breeder (Wells 1977. Anim. Behav. 27:666–693). Although males may physically compete for calling sites (Fellers 1975. Chesapeake Sci. 16:218–219), to our knowledge, attempts by males to dislodge other males in amplexus have not been reported.

On 6 June 2002 we observed a number of males (at least 3) calling loudly in a small area (ca. 660 cm circumference). We then noticed a pair in amplexus near the calling males. One of the calling males jumped and landed within a few centimeters of the pair and attempted to dislodge the male from the female with its forelegs. The female then jumped to a location more central to the calling males while remaining in amplexus. Shortly thereafter the three males began calling vigorously, converged in the same area near the pair, and began grappling with each other. As a result, the interfering male was pushed into the water. The interfering male then crawled out of the water calling loudly and moved directly towards the pair in amplexus. When the interfering male was within a few centimeters of the pair, it jumped at the pair. The female then jumped, while still in amplexus with the original male, to a location on the opposite side of a tree that was above the calling males. Within a few minutes the remaining males ceased calling and their activity decreased.

These observations occurred in a swamp where the predominant vegetation is willow (*Salix* sp.) near the Lafayette Regional Airport, Lafayette Parish, Lafayette, Louisiana, USA (30°11'88"N, 91°59'09"W). Weather conditions at the Lafayette Regional Airport at 2253 h were 26°C, 78% humidity, 1012.0 hPa pressure, 16.1 k visibility, 7.4 km/h wind speed, clear sky, and 0 precipitation.

We thank Robert G. Jaeger for providing comments on an earlier draft. Funding was provided by the Louisiana Board of Regents Doctoral Fellowship grant LEQSF(2000-05)-GF-30 to K. A. Roberts through R. G. Jaeger and from The Graduate Student Organization of The University of Louisiana at Lafayette.

HYLA MIOTYMPANUM (Small-eared Treefrog). **PREDATION**. *Hyla miotympanum* occurs in highland cloud forests from Nuevo León to Oaxaca and central Chiapas in eastern México (Frost 2002. Amphibian Species of the World: An Online Reference V2.21). Although widely distributed and relatively abundant, there is little published information about the natural history of *H. miotympanum*. Herein is the first report of an adult *H. miotympanum* being preyed upon by a water bug (*Abedus* sp.:

Belostomatidae).

At 2230 h on 24 May 2002, a male *Abedus* carrying eggs on its back was found sucking the body fluids from a young adult *H. miotympanum* underwater in a permanent stream. These observations were made near Coatepec, Veracruz, México (19°27'29"N, 96°59'04"W, 1180 m elev.) in a remnant cloud forest surrounded by shade coffee, where these frogs are abundant. This observation suggests that aquatic insects are a source of mortality even during the terrestrial life cycle of these frogs. The frog and the water bug were photographed at the stream. I thank José Antonio Gómez for identifying the belostomatid.

OSTEOPILUS SEPTENTRIONALIS (Cuban Treefrog). **DIET**. *Osteopilus septentrionalis* is a large hylid introduced to Florida (USA) and is common around buildings and in disturbed areas in southern parts of the state. It feeds on a variety of prey, including several vertebrate species (Meshaka 2001. The Cuban Treefrog in Florida. University Press of Florida, Gainesville. 192 pp.). This note documents *O. septentrionalis* predation on *Storeria victa* (Florida brownsnake), a previously unreported prey item.

O. septentrionalis has been observed on many occasions in the outdoor shower near a house within the boundaries of Big Cypress National Preserve, Ochopee, Collier County Florida, USA. On 6 February 2002 at approximately 2000 h, a large (> 60 mm) *O. septentrionalis* was discovered clinging to a bathroom door with the head and a short portion of the body of a *Storeria victa* protruding from the mouth of the frog (Fig. 1). After taking a photograph, we captured the frog and removed the snake from its mouth for positive identification. The snake had suffered several lacerations, but was able to move away without difficulty upon release.

This is the first account of *O. septentrionalis* in Florida feeding on a native squamate. Meshaka (2001) reported three squamate species in the diet of *O. septentrionalis* in Everglades National Park, but these were all species of introduced lizards. As *O. septentrionalis* continues to expand its range in Florida and increasingly invades natural areas, it may incorporate other native vertebrate species into its diet.

FIG. 1. *Osteopilus septentrionalis* with *Storeria victa* protruding from its mouth.

PHYSALAEMUS CUVIERI (Barker Frog). **PREDATION.** Aquatic invertebrates, especially belostomatids, are often cited as tadpole predators (Eterovick and Sazima 2000. Amphibia-Reptilia 21:439–461). However data on adult frog predation by belostomatids are scarce (see Bastos et al. 1994. Herpetol. Rev. 25:118; Haddad and Bastos 1997. Amphibia-Reptilia 18:295–298). *Physalaemus cuvieri* is a small leptodactylid frog that occurs in northeastern, central, and southern Brazil, and in adjacent Argentina and Paraguay (Frost 1985. Amphibian species of the world. Allen Press, Lawrence, Kansas, 732 pp.). It is common in open, wet areas, including preserved and anthropic habitats, and is the most abundant leptodactiylid at the Itirapina Ecological Station (IES; 22°13'24"S 47°54'03"W; ca. 750 m elev.), São Paulo State, southeastern Brazil. The reserve includes different, well-preserved Cerrados (savanna-like vegetation).

On 8 Dec 2001 at ca. 2200 h we found an adult male *P. cuvieri* (29.9 mm SVL) being preyed upon by a belostomatid, *Belostoma* aff. *ellongatum* (35.3 mm body length, 13.4 mm body width) on the surface of a temporary pond. The belostomatid was holding the frog by the head with its raptorial forelimbs. We captured and preserved both animals. The frog had a large cut (4.7 mm long) on the right side of the gular region, probably caused by the belostomatid proboscis (Haddad and Bastos 1997. *op. cit.*). *Physalaemus cuvieri* calls and lays its eggs on the water of temporary ponds that usually have high densities of belostomatids and may thus be vulnerable and probably often preyed upon by these aquatic invertebrate predators. Voucher specimens of *P. cuvieri* and the belostomatid are deposited in the Museu de História Natural, Universidade Estadual de Campinas (ZUEC 12046).

We thank D. Zanchetta and the staff of Instituto Florestal that facilitated our fieldwork at IES. Funding was provided by the FAPESP (00/12339-2; 99/06245-6; 99/05664-5). We thank Marcio Martins for suggestions on the manuscript, and Carlos Campaner for the identification of the belostomatid. This is the publication number 10 of the project Ecology of the Cerrados of Itirapina.

RANA CAPITO. (Gopher Frog). **DROUGHT SHELTER**. During extreme drought, much of the former stream bottom of a small tributary of the Ochlockonee River, Leon County, Florida, USA, was exposed and dried to non-vegetated banks, partially covered with broken-off limbs from overhanging willow trees (*Salix* sp.). The limbs had been submerged, and the bark, phloem, and inte-

rior portion had decomposed leaving brittle tubes of dense secondary xylem. In traversing these banks during mid-afternoon on 26 May 2000, several of these brittle limbs were broken, and on three instances *R. capito* (N = 4) were dislodged from the hollow interiors of these limbs. None of the limbs were more than 5 cm in diameter at the breaking point, and none of the breaking points were in direct contact with the ground. The concentration of these limbs suggests that they could provide significant shelter for a small population of *R. capito* at this site.

Submitted by **MAX A. NICKERSON** and **SOPHIA FELICIANO CELINO**, University of Florida, Florida Museum of Natural History, P.O. Box 117800, Gainesville, Florida 32611-7800, USA; e-mail: (MAN): maxn@flmnh.ufl.edu.

RANA CASCADAE (Cascade Frog). **CANNIBALISM.** Although cannibalism has been reported for several species of ranid frogs in western North America (Pilliod 1999. Herpetol. Rev. 30:93; Licht 1986. Can. Field Nat. 100:22–31), cannibalism in *Rana cascadae* has not been documented. We report observations made on 12 July 2001 of intraspecific predation by post-metamorphic *R.cascadae* in the Cascade Mountains of Oregon, USA. We observed the behavior of five adult (50–65 mm SVL) and two subadult (35–40 mm SVL) *R. cascadae* around East Snow Lake (43°02'04"N, 123°29'9"E), which had dried down to a 3 m x 5 m pool < 0.5 m deep. We estimated ca. 7500 *R. cascadae* larvae and metamorphs (mean SVL 20 mm, N = 10), and ca. 5000 smaller Pacific treefrog (*Hyla regilla*) larvae (mean SVL 10 mm, N = 10) were present in and immediately around the pool.

At ca. 1400 h, we observed a *R. cascadae* subadult (ca. 35 mm SVL) at the water's edge capture and consume a *R. cascadae* larva (ca. 20 mm SVL) that had come to the surface. The subadult lunged forward and engulfed the body of the larva in a single motion, and ingested the tail with a second jaw movement. The entire episode lasted 1–2 seconds. Approximately two minutes later, we observed an adult *R. cascadae* (59 mm SVL) capture and consume a metamorphic *R. cascadae* (ca. 18 mm SVL). The adult *R. cascadae* hopped ca. 20 cm down the bank toward the metamorph as it emerged from the water. The metamorph remained motionless for ca. 10 sec, and upon movement, was captured and swallowed in a single motion. We subsequently examined four adult male *R. cascadae* (50–63 mm SVL) from around the pond. Palpation of their stomachs suggested each frog contained 1–3 large food items consistent in size, shape, and texture with anuran larvae or metamorph prey.

As adult anurans are not believed to distinguish conspecifics from other prey (Duellman and Trueb 1986. Biology of Amphibians, John Hopkins University Press, Baltimore, 246 pp.), this observation of cannibalism likely represents a response to an abundant food source. Conspecifics represent a potential source of nutrition for adult anurans recovering from the physical demands of breeding and preparing for extended winter inactivity (Lannoo et al. 1989. Can. J. Zool. 67:1911–1914; Crump 1990. Copeia 1990:560–564).

We thank M. J. Adams and R. Hoffman for their reviews of this manuscript. This work was funded by the USGS State Partnership Program. Animals were handled under a Scientific Collecting Permit from the Oregon Department of Fish and Wildlife.

TESTUDINES

APALONE FEROX (Florida Softshell Turtle). **MOVEMENT BEHAVIOR.** Very little is known about the terrestrial movement behavior of *Apalone ferox* (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 578 pp.). In fact, detailed information on the terrestrial movements of aquatic turtles in general is sparse (Gibbons 1970. Amer. Midl. Nat. 83:404–414). Here we report terrestrial movement behavior of an individual *A. ferox*.

On 24 July 2001 at 1500 h one of us (JEC) found an *A. ferox* on a 10 m wide road consisting of a sand substrate at the Archbold Biological Station, Highlands County, Florida, USA. Ambient temperature was 33°C in shade and relative humidity was 64%. The individual was brought into the laboratory and measured and weighed (293 mm CL, 2.3 kg) and was most likely a male because the vent was near the tip of the tail (Ernst et al., *op. cit.*). Tracks of the individual showed that it had moved 264 m north in a straight line along the sand road. We traced the tracks to where the turtle had entered the sand road from an area of old cattle pasture on the east side of the road. On 25 July 2001 at 1500 h we released the *A. ferox* at the capture site. Later that evening we returned and found that it had continued its northward travel, in a straight line, for 68 m, then turned east and traveled 8 m. At that point the turtle entered a gate in a fence and the tracks were lost in the grass. A pond was located ca. 80 m to the east of the last tracks.

This observation is important for three reasons. One, the terrestrial movement behavior occurred in very hot conditions, surprising given the rate of water loss (14.4 g/h) for a congeneric of approximately the same size at 35°C in the lab (Robertson and Smith 1982. Physiol. Zool. 55:124–129). However, the high relative humidity (64%) may have lessened desiccation. Second, 16.5 cm of rain fell 20-23 July at this locality, with no rain falling on 24 July, suggesting that terrestrial movement of *A. ferox* occurs after heavy rains. Third, the *A. ferox* appears to have moved in a relatively straight line, along the dirt road, toward a pond.

Submitted by **KYLE G. ASHTON** and **JANE E. CARLSON***, Archbold Biological Station, 123 Main Drive, Venus, Florida 33960, USA; *present address: Department of Natural Resources, Cornell University, Ithaca, New York 14853, USA.

CARETTA CARETTA (Loggerhead Sea Turtle). **NEST ARCHITECTURE.** No studies have compared nest architecture among populations of sea turtles. We compared nest architecture in loggerhead sea turtles at natural beaches in Florida, USA and Brazil to determine how similarities and differences in female morphology and reproductive output in these two populations are reflected in the structure of the nest. There is no significant difference between loggerheads nesting in Florida and Brazil for straight carapace length (distance from middle of nuchal to pygal

notch), mean hind flipper length (distance from proximal end of tibia to the distal tip of the longest digit, averaged for the two flippers), and clutch volume, but Brazilian loggerheads have a larger straight carapace width (widest point across carapace) and lay larger clutches of smaller sized eggs in deeper nests (Tiwari and Bjorndal 2000. Herpetologica 56:343–356).

Data were collected from 33 nests in Melbourne Beach, Florida, USA, in 1993, and from 14 nests from Busca Vida Beach in Bahia, Brazil, in 1995. We measured loggerheads, after they completed nesting, for straight carapace length, straight carapace width, and mean hind flipper length. Eggs were removed from each nest and counted; yolkless eggs were excluded from the counts. The clutch was reburied in a nest chamber dug nearby.

To create a nest cast, an expanding polyurethane foam was sprayed into the empty nest cavity, left to cure, and excavated a few hours later (Carthy 1996. The Role of the Eggshell and Nest Chamber in Loggerhead Turtle [*Caretta caretta*] Egg Incubation. Ph.D. dissertation. Univ. Florida, Gainesville. 123 pp.). From the excavated nest cast, main chamber length (CL) and width (CW), and nest neck length (NL) and width (NW) were recorded (Fig. 1). Nest volume (NV) was determined by quantifying the amount of water displaced when the cast was immersed. This comparison of nest architecture is limited to the nest chamber excavated by the hind flippers.

Cast measurements were compared between sites using t-tests. Equality of variances was analyzed using Levene's test. To determine if body size measurements and clutch size were correlated with chamber length, chamber width, and nest volume, least square regression analyses were used. Alpha level was set at 0.05. Analyses were conducted with SPSS 10.0 software.

Variances for all variables were homogeneous between the two beaches. Mean values of chamber length and width, nest neck length and width, and nest volume did not differ between Florida and Brazil ($P > 0.05$). The mean value (SD) [range] and sample size for each of the preceding variables were: Florida: CL = 25.1 cm (3.0) [17.8–30.8], N= 33; CW = 23.8 cm (4.2) [13.6–30.7], N = 33; NL = 20.3 cm (1.9) [17.6–24.6], N = 33; NW = 15.8 cm (2.6) [11.2–20.4], N = 33; NV = 11030.0 ml (1825.3) [8360–14260], N =21; Brazil: CL = 25.8 cm (2.5) [22.2–29.2], N = 12; CW = 25.2 cm (2.5) [20.4–29.2], N = 12; NL = 19.3 cm (1.7) [17.2–22.6], N = 14; NW = 16.1 cm (1.9) [11.7–18.8], N = 14; NV = 11757.1 ml (2574.3) [7755–15835.7], N= 11. Straight carapace length and mean hind flipper length were not correlated with any nest measurements in Brazil or Florida ($P > 0.05$). Clutch size was not correlated with any cast measurement ($P > 0.05$) except with chamber width in Florida ($r^2 = 0.22$, $P = 0.04$, $N = 20$). Straight carapace width was also correlated with chamber width in Florida ($r^2 = 0.22$, $P = 0.03$, $N = 21$), but not in Brazil ($P > 0.05$). Significant correlations of chamber width with clutch size and straight carapace width in Florida but not Brazil may be due to differences in nesting media between the two beaches or in sample sizes. Sand characteristics were not compared between the two sites.

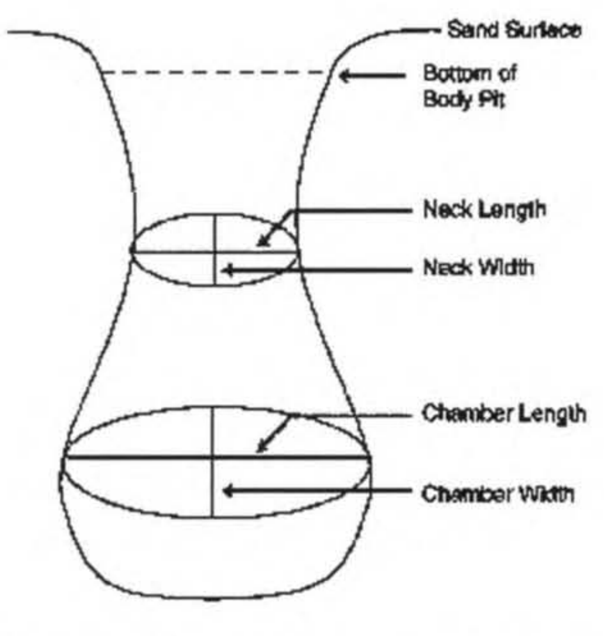

FIG. 1. Neck and chamber measurements taken from loggerhead seaturtle nest casts in Florida and Brazil. Nest volume was measured from the bottom of the body pit.

Understanding nest architecture is essential for conservation programs that relocate nests, to ensure that an appropriate incubation environment is reconstructed for the eggs. Future studies addressing the relationship between nest architecture and the incubation environment could provide important insights into embryonic development (Billes and Fretey 2001. Marine Turtle Newsletter 92:7–9).

We thank N. Marcovaldi and Projeto Tamar (Brazil) and L. Ehrhart and his crew (Florida) for their help and support. Our thanks to A. Bolten who helped develop this project. We are grateful to all of the volunteers in Brazil and Florida who helped with nest casting. S. Balcomb and G. Pryor provided comments on early drafts. Funding for this project came from the Lerner-Gray Fund of the American Museum of Natural History, the University of Florida Grinter Fellowship, and the U.S. Fish and Wildlife Service. The project was approved by the Institutional Animal Care and Use Committee, University of Florida; the Florida Department of Environmental Protection; and Projeto Tamar, Brazil.

CHELONIA MYDAS AGASSIZII (East Pacific Green Seaturtle). **DIET**. The feeding habits of *Chelonia mydas agassizii* have been documented for much of its range (Felger and Moser 1987. Environ. Southwest, Fall 1987:18–21; Casas-Andreu and Gomez-Aguirre 1980. Bolm. Inst. Oceanogr., S. Paulo, 29:87; Seminoff et al. 2002. J. Herpetol. 36:447–453). Although immature and adult *C. mydas agassizii* are known to be primarily herbivorous, feeding on seagrasses and/or marine algae, this turtle occasionally consumes invertebrates (Casas-Andreu and Gomez-Aguirre, *op cit.*; Felger and Moser, *op cit.*; Seminoff et al. 2000. Herpetol.

Rev. 31:103). Here we report on the consumption of pelagic red crabs (*Pleuroncodes planipes*) by a *C. m. agassizii* along the Pacific Coast of the Baja California peninsula, Mexico.

Between October 2000 and March 2002, we examined digestive tract contents of 23 turtles that were incidentally drowned in fishing nets near Bahía Magdalena, Baja California Sur, México (24°15'–25°20'N and 111°20'–112°15'W). On 12 February 2002, we recovered a stomach from an immature *C. mydas agassizii* (straight carapace length = 54.4 cm) containing more than 82% by volume of red crabs (*Pleuroncodes planipes*). *P. planipes* has been shown to be a primary food of Loggerhead Seaturtles (*Caretta caretta*) in the Pacific Ocean (Ramirez-Cruz et al. 1991. Archelon 1[2]:1–4), but to our knowledge this is the first report of red crab consumption by a *C. m. agassizii*, and the first documentation of a Green Seaturtle feeding predominantly on crustaceans. The highest densities of *P. planipes* in the eastern Pacific Ocean occur off Bahía Magdalena; the crabs migrate inshore during cold season (winter–spring) upwelling conditions (Aurioles-Gamboa 1992. Crustaceana 62:71–84). This finding is consistent with reports by Bjorndal (1997. *In* Lutz and Musick [eds.], The Biology of Sea Turtles, pp. 199–232. CRC Press, Boca Raton, Florida) that East Pacific Green Seaturtles may have a more carnivorous diet than *Chelonia* of other regions.

We thank the CIBNOR (Centro de Investigaciones Biologicas del Noroeste, S. C.) for providing financial support for this field study.

PSEUDEMYS PENINSULARIS (Peninsula Cooter). **ESTUARINE OBSERVATION and INTERACTION WITH GIANT LAND CRABS**. At 0710 h, 11 June 2002, a *Pseudemys peninsularis* was found in a Giant Land Crab (*Cardisoma guanhumi*) colony on an isolated isthmus of sandy spoil in a large bulkheaded estuarine canal (Intracoastal Waterway) near Woolbright Road in Boynton Beach, Florida. The spoil site was adjacent to the concrete seawall of the canal and rose < 0.5 m above the mean high tide level. The turtle was found on its back, partially covered by a fallen palm frond, and was surrounded by 20–25 easily visible crabs within 10 m, and three were within 15 cm at the initial sighting. The turtle was deeply retracted into its shell, and its right rear foot exhibited soft tissue damage apparently inflicted by crabs. It was released at ca. 0713 h into 0.25 m deep water adjacent to the island, where it remained submerged and deeply retracted into its shell when observations ended at 0720 h.

The crab colony is an isolated, triangular 255 m^2 area containing 494 burrows > 5 cm diameter, for an average density of 1.94 burrows/m^2. The crab colony has existed at this site since at least 1993 (HS, pers. obs.). The dominant vegetative cover is Sea Oxeye (*Borrichia frutescens*). The cooter was an immature female based on toenail length and tail morphology with a carapace length of 14 cm (Jackson 1988. Bull. Florida State Mus. Biol. Sci. 33[3]:113–158; D.R. Jackson, pers. comm.). Rain had fallen for at least 0.5 h ending 10–15 min prior to finding the turtle. The air temperature was estimated to be 26–29°C.

The turtle's presence in this habitat was unusual, as this species is not normally found in coastal salt waters. The salinity of the water in this canal is 26.9–30.8 parts per thousand (G.H. Powell, Palm Beach County Dept. Environ. Resources Mgmt.). In 9 years of observation, no other freshwater turtles have been observed at, or near, this site. Its presence on the spoil pile was likely not related to nesting since the turtle was below minimum size for reproduction (Jackson, *op. cit.*; D. R. Jackson, pers. comm.). We speculate that the turtle was either washed or released into the estuary, attempted to seek refuge from the salinity or bask on the area with the crab colony, and was unable to escape when attacked by the crabs.

CROCODYLIA

CAIMAN CROCODILUS YACARE (Pantanal Caiman). **FOOD-RELATED MOVEMENT**. Crocodilians move for many reasons (Lang 1987. *In* Webb, Manolis and Whitehead [eds.], Wildlife Management: Crocodiles and Alligators, pp. 273–294. Surrey Beatty & Sons, Chipping Norton, New South Wales). *Caiman crocodilus yacare* occur in high densities in seasonally flooded habitats in the Brazilian Pantanal (Coutinho and Campos 1996. J. Trop. Ecol. 12:741–747), and food shortages during the dry season have the potential to influence movement. As Santos et al. (1996. Herpetol. J. 6:111–117) mentioned large number adults and tadpoles of *Pseudis paradoxa* (or soaps) in diet of caimans in the brackish ponds, here I report changes in caiman density potentially linked to changes in soap density in a lake in the Brazilian Pantanal.

Observations were made on the Nhumirim Ranch (18°59'S, 56°40'W), Mato Grosso do Sul, Brazil over the period 1989–1999. During night surveys, caiman were counted and soap densities were estimated. One alkaline lake (pH of 9.0–9.9) generally had relatively few (10–34) caiman during each of 20 times it was surveyed. Only two surveys recorded high densities of caiman (> 500), but each coincided with high densities of *P. paradoxa*. In each case, I estimated soap densities on the edge of the lake to be > 100 adults and large tadpoles/m^2. On 10 April 1999, we marked 20 caiman of the several hundred present in the lake during the soap eruption. After 150 days, one marked female was recaptured in a river area 5 km away and the total number of caiman we detected in the lake was reduced to 20. These observations suggest that caiman move in response to changes in prey density.

I thank Sandra Santos and Max Pinheiro for help with surveys in 1989 and Henrique de Jesus, José Augusto Silva and Vandir Silva for assistance with capture of caiman.

PALEOSUCHUS TRIGONATUS (Dwarf Caiman). **NEONATE TIME BUDGET**. Natural history of forest-dwelling animals is often poorly understood because of the difficulties in observing them. Further, studying neonates can be especially difficult as their small size and cryptic nature limits field observation (Morafka et al. 2000. Herpetol. Monogr. 14:353–370). Dwarf caiman, *Paleosuchus trigonatus*, are no exception to this pattern. Few studies have dealt with their natural history (Magnusson et al. 1991. J. Herpetol. 25:41–48; Rivas et al. 2001. Herpetol. Rev. 32:251), and none have addressed neonate behavior. Here, we present preliminary observations on the behavior of neonate *P. trigonatus* in a creek in the Tiputini River (Amazonian Ecuador) during March 2000.

On 30 September 1999, we discovered a *P. trigonatus* nest in a low stature, seasonally-flooded varzea forest 4.5 m from the base of a tree from a small creek. Based on finding eggshells characteristic of recent hatching, at least 12 neonate dwarf caiman are thought to have emerged from this nest on 27 November 1999 (Rivas et al., *op. cit.*). Five neonate dwarf caiman (mean total length = 30.6 cm, range: 29.9–32.8; mean mass = 103 g, range: 85–120 g) found 19 March 2000 in a small stream (mean width = 1.6 m, mean depth = 0.2 m) < 50 m away are believed to have originated from this nest. To study the time budget and behavior of these neonates, we conducted night observations from 1900 to 0600 the next day. During night observation periods, we recorded the behavior of as many neonates as we could find. We found 4, 2, and 1 neonate dwarf caiman, respectively, on 22, 29, and 30 March 2000. As we did not handle the animals prior to observations, we were unable to determine whether we saw the same animals on different nights; we pooled all data across nights for analysis. We recorded data every 10 min on each animal (using their eyeshine) by turning on a dim flashlight for a brief (5–10 sec) interval. The neonate's head position relative to the water surface (as low [eyes barely showing], intermediate [upper but not lower jaw above waterline] or high [lower jaw at least partly out of water]) and its distance from shore/water edge (cm) was recorded at each interval. We also estimated height over the water (in m) of the lowest plant that directly overhung each caiman, potentially concealing it from possible predators. If an animal was present early in the night and disappeared from one observation interval to the next, we assumed that it was hiding or under the water. We were monitoring a long (ca. 30 m) stretch of creek and neonates were unlikely to have moved out of the area.

We made 410 observations of neonate *P. trigonatus*. Neonates spent most of their time (91%; N = 266) within 0.5 m of shore; relatively little time was spent mid-stream far from the bank. Neonate *P. trigonatus* were also found beneath relatively low overhanging vegetation (i.e., within 1 m of the water surface) 62% (N = 190) of the time, which may indicate selection for relatively sheltered areas. Neonate dwarf caiman were immobile in 51% (N = 206), out of sight (probably immobile as well) in 27% (N = 112), and active in only 22% (N = 91) of the observations. Neonates changed locations between observations more often before 2300 and were more frequently concealed after 0200. Most of the time (83%; N = 246), neonate *P. trigonatus* held their heads high. Holding the head elevated has been associated with territorial behavior in caiman (Verdade 1999. Herpetol. Rev. 30:38–39). Lack of aggregation among neonates, a feature of clutch pods among many crocodilians; lack of distress calls during our periods of observation; and absence of adult dwarf caiman reported previously for this creek (Rivas et al., *op. cit.*) collectively suggests that the neonates we observed may already be on their own, implying that parental protection in this species, if it exists, is short-lived.

During the two months that we spent surveying caimans in the area, we did not detect any other dwarf caiman of a size similar to these neonates in the Tiputini River. However, we regularly saw juvenile (< 20 cm SVL) spectacled caiman (*Caiman crocodilus*) and larger dwarf caiman (≥ 40 cm SVL) using the main river. Neonate dwarf caiman may rear in small forest streams with dense forest vegetation because they gain greater protection from predators in such habitat. If true, deforestation of small forest streams, like this one, may seriously impact the survival of neonate dwarf caiman.

Data for this contribution were collected during a course of tropical ecology by Boston University and Universidad San Francisco de Quito at Tiputini Biodiversity Station. We thank Mayer Rodriguez, Hendry Narváez, Franklin Narváez, Jaime Guerra, and Bradley Kline for their help in the field work and Kelly Swing for comments on early versions of the manuscript.

LACERTILIA

ANOLIS PORCATUS (Cuban Green Anole). **NECTIVORY**. *Anolis porcatus* is a moderate-sized Cuban anole that has become established in Miami-Dade County, Florida (Meshaka et al. 1997. Herpetol. Rev. 28:101–102). In its native habitat, *A. porcatus* is known to eat insects, particularly odonates (Schwartz and Henderson. 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distribution, and Natural History. Univ. Press of Florida. 720 pp.). Further, Meshaka et al. (*op. cit.*) reported a varied invertebrate diet and occasional consumption of smaller lizards and fruit for introduced *A. porcatus* in Florida, but nectivory is undocumented. Nectivory has been recorded in three other anoles, *A. consperus*, *A. stratulus*, and notably *A. carolinensis* (which is closely related to *A. porcatus*). The latter reportedly consumes the nectar of two native palms, *Serenoa repens* and *Sabal palmetto*, in central Florida (Campbell and Bleazy 2000. Herpetol. Rev. 31:239). Herein, I document the first report of nectivory in *A. porcatus* introduced to Florida.

At 1135–1141 h on 9 May 2002, I observed an adult male *A. porcatus* lapping nectar from and consuming the blossoms of an ornamental areca palm (*Chyrsalipedocarpus lutescens*) in a yard near SW 162nd Street and Old Cutler Road in Miami, Florida. The lizard moved from a basking site on the stem of a leaf directly onto a flowering inflorescence, and immediately began to extract nectar from each of the small flowers with its tongue. The anole visited at least 14 flowers, while moving along the inflorescence,

carefully lapping the nectar from each flower. At least once, the lizard ate a flower that became dislodged from the inflorescence. The portion of the diet of *A. porcatus* comprised of *C. lutescens* flowers is unknown, but these introduced lizards are at least opportunistic feeders on the flowers of some non-native ornamental palms.

I thank Robert Powell for suggestions on a draft of this note. The lizard (UF 132470) was deposited in the Florida Museum of Natural History herpetological collection.

Submitted by **JOSIAH H. TOWNSEND**, Department of Wildlife Ecology and Conservation, University of Florida, and Division of Herpetology, Florida Museum of Natural History, Gainesville, Florida 32611, USA; e-mail: jtownsend@flmnh.ufl.edu.

CNEMIDOPHORUS HYPERYTHRUS (Orange-throated Whiptail). **ENDOPARASITES**. Two reports of endoparasites from *Cnemidophorus hyperythrus* exist: Bostic (1965. Southwest. Nat. 10:313) reported that of 104 individuals, 5 (prevalence 5%) harbored the cestode *Oochoristica bivitellobata*, 17 (prevalence 16%) harbored unidentified oxyurid nematodes, and one (prevalence 1%) harbored a nematode of the genus *Pharyngodon*; Telford (1965. Japan J. Exp. Med. 35:111–114) described the nematode *Thubunaea iguanae* from specimens taken from *C. hyperythrus* and 12 other lizard species (prevalences not reported). Here, we report a second nematode species, *Pharyngodon warneri*, from *C. hyperythrus*.

Thirty-one *C. hyperythrus* (mean SVL = 59 mm, ± 4 SD, range: 49–68 mm) from the herpetology collection of the Natural History Museum of Los Angeles County, Los Angeles (LACM 99852–99855, 99859–99860, 99862–99878, 99880, 150800–150806), collected in Riverside County, California were examined for helminths. The body cavity was opened by longitudinal incision from throat to vent and the digestive tract removed. The esophagus, stomach, small and large intestines were opened and separately examined for helminths under a dissecting microscope. The body cavity was also searched for helminths. Nematodes were cleared in a drop of undiluted glycerol on a glass slide and cestodes were regressively stained in hematoxylin and mounted in Canada balsam before identification using a compound microscope. One species of Cestoda, *Oochoristica bivitellobata* and one species of Nematoda, *Pharyngodon warneri* were found. Selected specimens were deposited in the United States National Parasite Collection, Beltsville, Maryland: *Oochoristica bivitellobata* (USNPC 92221); *Pharyngodon warneri* (USNPC 92222). Prevalence, mean intensity (mean number of helminths per infected lizard) and range for *O. bivitellobata* was 6%, 3.0 ± 2.1 SD, 1–4; for *P. warneri*, 19%, 6.0 ± 5.4 SD, 1–14. Hosts of *O. bivitellobata* and *P. warneri* were summarized in Goldberg et al. (1997. Great Basin Nat. 57:273–277). *Urosaurus ornatus* should be added to the host list of *P. warneri* (Walker and Matthias. 1973. Proc. Helminth. Soc. Washington 40:168–169). *Cnemidophorus hyperythrus* represents a new host record for *P. warneri*.

We thank D. A. Kizirian (Natural History Museum of Los Angeles County) for permission to examine specimens.

COLEODACTYLUS MERIDIONALIS (NCN). **DIET**. *Coleodactylus meridionalis* is a litter-dwelling gekkonid lizard distributed in the Caatinga and Atlantic Rainforest of northeastern Brazil (Vanzolini et al. 1980. Répteis das Caatingas, Academia Bras. Ciências, São Paulo. 161 pp.). Information about its ecology is scarce with virtually no data on the species' feeding habits. A few data on the species come from the Caatinga region and from forest habitats in the Atlantic Rainforest (Vanzolini et al., *op. cit.*; Freire 1999. Bol. Mus. Nac., Rio de Janeiro 399:1–14) but no ecological information exists about the species from "restinga" habitats (coastal herbaceous and shrubby sand dunes), distinctive habitats within the Brazilian Atlantic rainforest ecoregion. Here, we report information on the diet of *C. meridionalis* based on stomach content analysis of six individuals from two restinga areas in the State of Bahia, northeastern Brazil.

Observations were made on 2 *C. meridionalis* (a 21.8 mm SVL male and a 21.1 mm SVL female) from Dunas de Abaeté in the Municipality of Salvador (12°57'03"S, 38°22'30"W) and 4 others (three males, 18.0, 19.5 and 20.6 mm SVL and 1 female, 21.2 mm SVL) from Baixio in the Municipality of Esplanada (12°06'01"S, 37°41'4"W). Lizards were dissected, and food items identified and counted. One lizard, a female from Baixio, had an empty stomach. Thirteen prey items were found in the five other lizards. Number of prey items per stomachs varied from 1 to 6, but most had < 3. *Coleodactylus meridionalis* ate eight prey groups (Araneae, Diptera, Hymenoptera, Isopoda, Isoptera, Lepidoptera larvae, Orthoptera and Pseudoscorpionida). Except for Isoptera and Pseudoscorpionida (where three and two individuals were eaten, respectively), we found one individual from each prey group. Based on volume, Orthoptera (45%), Isopoda (32%), and Araneae (15%) were the dominant groups. All prey groups had the same percentage occurrence per individual (16%). Data on the congeneric *C. amazonicus* from the Brazilian Amazon indicate a diet composed mostly of Collembola and Acarina (Ramos 1981. Acta Amazonica 11:511–526), prey not found in the *C. meridionalis* we examined.

Voucher specimens of *C. meridionalis* were deposited in the collection of the Instituto de Biologia da Universidade Federal da Bahia (IBUFBA; LAG480–483, LAG554 and LAG558). We thank the Conselho Nacional do Desenvolvimento Científico e Tecnológico (CNPq, processes 300819-4 and 461970/00-7), Fundação de Amparo à Pesquisa do Estado do Rio de Janeiro (FAPERJ) for funding, and Marc Hayes, Davor Vrcibradic, and two anonymous reviewers for suggestions.

ELGARIA PANAMINTINA (Panamint Alligator Lizard). **REPRODUCTION**. The biology of *Elgaria panamintina* is summarized in Banta et al. (1996. Cat. Am. Amphib. Rept. 629:1–4). Information on clutch sizes or the timing of the events in the testicular cycle are unknown. Here we report the first clutch size and time of sperm formation (spermiogenesis) for this species.

Specimens were examined from the California Academy of Sciences (CAS), San Francisco, Natural History Museum of Los Angeles County (LACM), Los Angeles, Museum of Vertebrate Zoology (MVZ), University of California, Berkeley and Department of Biology, San Diego State University (SDSU), San Diego. All specimens were collected in Inyo County, California in the interval 1959–1985. Six males (mean SVL = 99 mm ± 9 SD, range: 90–114 mm) and two females (SVL = 105 mm ± 6 SD, range: 100–109 mm) were examined. In males, the left testis was removed and embedded in paraffin. Histological sections were cut at 5 mm, mounted on glass slides and stained with Harris' hematoxylin followed by eosin counterstain.

One male collected in May (CAS 89230, 93 mm SVL) was undergoing sperm formation (spermiogenesis). Lumina of the seminiferous tubules were lined by sperm. Two males collected in June (MVZ 77063, 97 mm SVL; CAS 89675, 92 mm SVL) had regressed testes containing spermatogonia. One male collected in June (MVZ 75918, 114 mm SVL) had a testis in early recrudescence (i.e., renewal of germinal epithelium for next period of spermiogenesis); spermatogonia and primary spermatocytes were present. One male collected in July (MVZ 227764, 90 mm SVL) had a regressed testis, a second male (MVZ 227765, 106 mm SVL) had a testis in recrudescence. The presence of a male collected in May undergoing spermiogenesis suggests that *E. panamintina* breeds during spring. This agrees with two other North American anguid lizards that also produce sperm at this time: *Elgaria multicarinata* (Goldberg 1972. Herpetologica 28:267–273) and *E. coerulea* (Vitt 1973. Herpetologica 29:176–183). A report of captive breeding in May exists for *E. panamintina* (Banta and Leviton 1961. Herpetologica 17:204–206). Behler and King (1979. The Audubon Society Field Guide to North American Reptiles and Amphibians. Alfred A. Knopf, New York. 743 pp.) reported spring mating for this species.

Histological examination revealed the ovarian follicles from the female collected in May (CAS 88135, 109 mm SVL) described in Banta (1963. Occas. Pap. California Acad. Sci. 36:1–12) as "developing eggs" had not started yolk deposition. One female collected in September (MVZ 150329, 100 mm SVL) contained 4 oviductal eggs and is the first clutch size reported for *E. panamintina.*

We thank J. Vindum (California Academy of Sciences), D. Wake (Museum of Vertebrate Zoology), and T. Reeder (San Diego State University) for permission to examine specimens.

BEAMAN**, Section of Herpetology, Natural History Museum of Los Angeles County, Los Angeles, California 90007, USA (e-mail: kbeaman@nhm.org).

EUMECES SEPTENTRIONALIS SEPTENTRIONALIS (Northern Prairie Skink). **NESTING BEHAVIOR**. Somma and Fawcett (1989. Zool. J. Linn. Soc. 95:245–256) reported nesting and brooding activity for *Eumeces septentrionalis* in the laboratory, but field observations of *E. septentrionalis* nesting behavior are restricted to the accounts of Breckenridge (1943. Amer. Midl. Nat. 29:591–606), Nelson (1963. Unpubl. Ph.D. dissertation, University of Minnesota, Minneapolis), and Somma (1990. Bull. Chicago Herpetol. Soc. 25:77–80). Here, I augment the limited field data on nesting in *E. septentrionalis* with observations on 3 nests from southern Iowa.

On 22 June 2000 at ca. 0800 h, I observed 3 different *E. septentrionalis* nests each with an associated female and each under a different cover object in an open, grassy field on the south edge of Bridgewater (town; 41°14'N, 94°40'W), Adair County. One nest was under a piece of cement, one was under a flat rock, and one was under a piece of tin. I had placed all cover objects at each location in previous years. Soil in the area was silt loam or silty clay loam. Each female skink was in a short, horizontal burrow (6–10 cm long, 3–6 cm diam opening) with eggs that were poorly visible because they were far back in each burrow. Nest locations were flagged and the cover objects replaced. I returned to the area at ca. 1000 h the same day to observe each nest once again. Close examination revealed that each female had placed her eggs (clutch sizes = 4, 9, 11) into a shallow depression (ca. 2 cm deep) located outside and adjacent to each burrow opening. Each clutch was in the open depression and clearly visible when the cover object was removed during the 1000 h visit. Nests were located in sparsely vegetated areas, which provided better insolation than in adjacent areas. Through apparent repositioning of the eggs to the outside of each burrow and directly under a cover object, the females may have been making the environment of each clutch thermally more favorable for development. Two of three nests I observed hatched by 18 July (< 30 days), over 10 days faster than those reported by Breckenridge (1943. Amer. Midl. Nat. 29:591–606). Based on brooding observations of *E. septentrionalis* in the lab, Somma and Fawcett (1989. Zool. J. Linn. Soc. 95:245–256) reported an incubation interval of < 23 days.

GAMBELIA SILA (Blunt-nosed Leopard Lizard). **PREDATION**. *Gambelia sila* is a fairly large member of the depauperate lizard fauna of California's San Joaquin Valley (Montanucci 1968. Herpetol. 24:316–320). This lizard, state and federally listed as endangered, remains over only about 15% of its historical range (Germano and Williams 1992. Trans. West. Sec. Wildl. Soc. 28:38–47). Understanding population dynamics, including potential predators, is essential to its recovery. Several predators of *G. sila* are known. These include two snakes, the San Joaquin coachwhip (*Masticophis flagellum ruddocki*) and gopher snake (*Pituophis catenifer*), and five birds, the prairie falcon (*Falco mexicanus*),

American kestrel (*Falco sparverius*), loggerhead shrike (*Lanius ludovicianus*), burrowing owl (*Athene cunicularia*), and roadrunner (*Geococcyx californianus*) (Montanucci 1965. Herpetol. 21:270–283; Tollestrup 1979. Ph.D. dissertation, University of California, Berkeley, 146 pp.; Germano and Carter 1995. Herpetol. Rev. 26:100). Here, we add two new species to the predator set on *G. sila*.

On 5 June 2002 at 0740 h, during a radio-telemetry study on the Lokern area of Kern County (California; 119°37'N, 35°22'W), we located the signal of a radio-collared *G. sila* coming from a northern Pacific rattlesnake (*Crotalus viridis oreganus*) that was curled up under a dead saltbush (*Atriplex* sp.). For the previous 5 days, we had located the signal in a burrow next to a wash ca. 3 m from where the rattlesnake was found. The area had burned in 1997, which killed native saltbush plants, and is one of 4 treatment replicates in a grazing study. Because of grazing and below-average rainfall in the previous winter, the land was largely devoid of herbaceous plants. We had tracked the *G. sila*, a small (100 mm SVL, 28.6 g) female, for 18 days. The rattlesnake, a small adult female (470 mm SVL and 74.6 g including the mass of the partially digested lizard and radio-telemetry package [2.2 g]), was euthanized by freezing. When the snake was opened, only the hind legs and tail of the lizard were recognizable (Fig. 1), which we think indicates that the lizard had been eaten several days prior to our finding it inside the rattlesnake.

On 23 May 2002, we captured an adult male *G. sila* (116 mm SVL, 53.6 g) in another part of the Lokern area. This area had not burned, was covered sparsely by living saltbushes, and was at the base of hilly terrain. We had taken 12 GPS locations until 18 June 2002, when the transmitter signal was determined to be coming from a distant location. We drove towards the signal (3.2 km straight-line distance) until we reached the base of a high-voltage powerline tower. The signal appeared to be coming from the nest of a pair of red-tailed hawks (*Buteo jamaicensis*), located ca. 30 m above the ground. We lost the signal 2 days later and were not able to recover the transmitter; we presume that one of the red-tailed hawks was responsible for the predation event. Although the northern Pacific rattlesnake and red-tailed hawk have been suspected as predators of *G. sila* (Tollestrup, *op. cit.*), these represent the first reports documenting, or suggesting, respectively, their preying on this lizard.

FIG. 1. Radiograph of the remains of a blunt-nosed leopard lizard (*Gambelia sila*) and its radio transmitter inside a northern Pacific rattlesnake (*Crotalus viridis oreganus*).

This work was carried out under U.S. Fish and Wildlife Service permit TE826513-1 and California Department of Fish and Game scientific collecting permit 801092-4 and accompanying memorandum of understanding. The rattlesnake (CAS 224701) was deposited with the California Academy of Sciences.

HOMONOTA UNDERWOODI (Underwood's Gecko). **BODY TEMPERATURE.** *Homonota underwoodi* is an insectivorous oviparous gecko that inhabits the dry hot landscape of the Monte Phytogeographic Province (Cabrera and Willink 1980. Biogeografía de América Latina. O.E.A. Washington D.C. 109 pp.) in Provincia de San Juan, Argentina. Like most Argentine gekkonids, few data address its biology. Werner *et al.* (1996. Cuad. Herp. 10:62–67), who made observations on body temperatures on a small number of lizards (N = 7), provided the only published data on this species' biology. Here, I augment the few data on field body temperatures as part of a larger study on this species' ecology.

Field work was carried out in a dry streambed with a mosaic of flagstones and patches of sand in La Laja, Departamento Albardon, Provincia de San Juan, Argentina (31°19'S; 68°41'W). Data were collected every 10 days from August 2000 to August 2001 by revisiting bushes and low flagstones across the study site at random. Each individual was captured by hand. The cloacal temperature (TC), temperature of the substrate (TS) and temperature of the air (TA) were measured with a rapid reading Miller-Weber thermometer to the nearest 0.1°C. For each capture, we took TS on the substrate at the exact point of observation, and TA 1 cm above the substrate. For both TS and TA, we distinguished whether the temperature was taken in the sun, shade or partial shade (on shrubby margins).

Of 56 captured animals, 96% were on low flagstones and 4% were in burrows among shrubs in an area heavily altered by human activities and erosion. Mean body temperature was 26.3°C (s = 5.6°C, N = 56). An ANOVA addressing gender differences in TC was not significant ($F_{2,50}$ = 1.61, P = 0.20). An ANCOVA (TS as the covariate) revealed no interseasonal differences in TC ($F_{2,50}$ = 2.30, P = 0.10). Cloacal temperature and TA were not correlated (r = 0.07, N = 56, P = 0.65), but the strong correlation between TC and TS was significant (r = 0.90, N = 56, P < 0.01). Evidence suggests that thermoregulation is enabled through conduction with the substrate and seems independent of air temperature. In contrast, Werner et al. (*op. cit.*), working with *H. underwoodi* on the Telteca Reservation NE of Mendoza (Argentina), obtained a significant correlation between TC and TA. These differences may be a function of the small number of lizards Werner (*op. cit.*) had. Body temperatures and the contrasts between TC and TS were similar in both studies. Lizards in the Telteca study thermoregulated under dry (livestock) dung patties during the day in a manner similar to what we observed in this population where low flagstones were consistently used.

CARLOS ACOSTA, and **HÉCTOR JOSE VILLAVICENCIO**, Departamento de Geofísica y Astronomía e Instituto y Museo de Ciencias Naturales, Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan, Avenida España 400 (N), Caixa Postal 5400, San Juan, Argentina (e-mail [JAM]: jamarineroar@yahoo.com.ar; [JCA]: jcacosta@sinectis.com.ar).

LEIOSAURUS CATAMARCENSIS (NCN). **CLUTCH SIZE.** *Leiosaurus catamarcensis* is one of three species of a genus endemic to Argentina. It occurs across the arid west, from Catamarca to south of Mendoza, reaching altitudes over 1800 m in the pre-Cordillera de San Juan (Cei 1986. Mon. IV Mus. Reg. Sci. Nat. Torino, 527 pp.). Its conservation status is ambiguous, and has been defined as a species for which "insufficient knowledge" exists (Lavilla et al. 2000. Categorización de los Anfibios y Reptiles de la República Argentina. Asoc. Herp. Arg. 97 pp.). No reproductive information exists for any *Leiosaurus* (Cei, *op. cit.*). Here, we present data on clutch size for a wild-caught *L. catamarcensis* that deposited eggs in captivity.

On 13 February 2002, we collected a gravid female (103 mm SVL) *L. catamarcensis* at Los Blanquitos, 3 km W Jachal (city), Departmento Jachal, Provincia de San Juan, Argentina (30°30'S; 68°15'W). This site is in the Monte Phytogeographic Province, where a shrubby vegetation and sandy terrain is characteristic (Cabrera and Willink 1980. Biogeografía de América Latina. O.E.A. Washington D.C., 109 pp.). This female was maintained in a 45 cm x 60 cm box with a sand substrate and fed crickets. On 5 March 2002, the female laid 10 eggs in the box. Length and width of each egg was measured with Vernier calipers to the nearest 0.01 mm. Volume of each egg was calculated based on Dunham (1983. *In* Huey et al. [eds.], Lizard Ecology: Studies of a Model Organism, pp. 261–280, Harvard University Press, Cambridge, Massachusetts). Eggs averaged 1.84 cm (s = 0.11) in length; 1.23 cm (s = 0.09) in width; and 1.44 cm^3 (s = 0.24) in volume.

Eggs were deposited in the Herpetological Collection, Instituto y Museo de Ciencias Naturales, Universidad Nacional de San Juan, Argentina.

Submitted by **GRACIELA BLANCO** and **JUAN CARLOS ACOSTA**, Departamento de Geofísica y Astronomía e Instituto y Museo de Ciencias Naturales, Facultad de Ciencias Exactas, Físicas y Naturales, Universidad Nacional de San Juan, Avenida España 400 (N), Caixa Postal 5400, San Juan, Argentina; e-mail (JCA): jcacosta@sinectis.com.ar.

LIOLAEMUS LINEOMACULATUS (NCN) **PREDATION.** *Liolaemus lineomaculatus* is a small lizard inhabiting the Patagonian steppe that is associated with open bunchgrass (*Stipa* sp., *Festuca* sp.) habitats (Cei 1986. Museo Regionale di Scienze Naturali, Monografie IV, Torino, Italy. 528 pp.). Cei (*op. cit.*) found a population probably referable to this species in Primeros Pinos (38°52'S, 70°34'W), Neuquén Province, ca. 290 km N of our site. Recently, new specimens were found in northern Río Negro and Chubut Provinces (Ibargüengoytía et al. 2001. Herpetol. Rev. 32:120). The specimen reported in this note represents the first record of predation on *L. lineomaculatus* by an Aplomado falcon (*Falco femoralis*) and the second record for Neuquén Province, implying that its distribution may be continuous along the Patagonian Andes from at least central Neuquén Province to the north to Santa Cruz Province to the south.

On 20 November 2001, we found an apparently road-killed Aplomado falcon with remains of a specimen of *Liolaemus lineomaculatus* in its stomach. The lizard was too digested to sex, but we estimated its size to be at least 44 mm SVL. The falcon was found on Route 237 (41°02'S, 71°09'W) in southern Neuquén Province, 22 km NE from the city of Bariloche, Río Negro Province, in Parque Nacional Nahuel Huapi, northwestern Argentine Patagonia. The Aplomado falcon is an open country predator which ranges from southern Texas and New Mexico to Tierra del Fuego (Ferguson-Lees and Christie 2001. Raptors of the World. Christopher Helm, London. 992 pp.). Its diet consists primarily of birds and insects (Hector 1985. Condor 87:336–342; Jiménez 1993. J. Raptor Res. 27:161–163; Bó 1999. Ornitol. Neotrop. 10:95–99). Although it has been recorded to occasionally prey on another species of *Liolaemus* in central Chile (*L. nitidus*: Jiménez, *op. cit.*), this record is the first for *L. lineomaculatus*.

We thank Nora Ibargüengoytía for identifying the *Liolaemus* specimen, and J. Brian Hauge and Marc P. Hayes for their valuable comments. The Delegación Técnica Regional Patagonia (Administración de Parques Nacionales) provided the authors the permit to collect the falcon specimen in Parque Nacional Nahuel Huapi.

Submitted by **ANA TREJO, SUSANA SEIJAS**, and **MERCEDES SAHORES**, Centro Regional Universitario Bariloche, Universidad Nacional del Comahue, 8400 Bariloche, Provincia de RÌo Negro, Argentina; e-mail (AT): strix@bariloche.com.ar.

SCELOPORUS MAGISTER UNIFORMIS (Yellow-backed Spiny Lizard). **PREY**. *Sceloporus magister* has been occasionally documented eating vertebrate prey, but only lizards (Stebbins 1985. Field guide to western reptiles and amphibians, 3rd ed. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). Vitt and Ohmart (Herpetologica 30:410–417) found a juvenile *Cnemidophorus tigris* in one stomach of this subspecies. Here we report the first mammal prey of *S. magister.*

At 1030 on 10 August 2002 at Cottonwood Spring, Riverside County, California (33°45'N; 115°32'W; elevation 900 m), we observed a large female *S. m. uniformis* with a small bat in its mouth. Based on its small size and light dorsal color, the bat was likely a western pipistrelle (*Pipistrellus hesperus*). The lizard was on the ground of the patio of the visitor center, where it is regularly seen. Bats roost frequently under nearby eaves. During the roughly 5 minutes that we observed this encounter, the lizard shook the bat vigorously several times, chewed on it, and dragged it. It disappeared from view while we were momentarily distracted by visitors. A subsequent search of the area failed to reveal either lizard or bat. As we did not observe the final outcome of this potential predation event, whether the lizard was able to swallow the bat is uncertain.

SERPENTES

ANILIUS SCYTALE (Red Pipesnake). **PREDATION**. *Anilius scytale* is a black-and-red colored, 70–90 cm long, semiaquatic, burrowing snake, native to equatorial South America east of the Andes (Greene 1997. Snakes: the Evolution of Mystery in Nature. University of California Press, Los Angeles, 351 pp.). We are unaware of any reports of predation on *A. scytale*. We report here an instance of predation on *Anilius scytale* by the roadside hawk, *Rupornis magnirostris* (Aves: Accipitridae). On 8 March 2002 at 1012 h we observed the hawk attacking a snake on an unpaved road besides a small creek (02°43'55"S, 44°17'31"W, 31 m elev.) in an area of Amazon Forest in São Luís, Maranhão, northeastern Brazil. With our approach, the hawk flew away carrying just the posterior part of the snake. Examination of the anterior portion of the snake revealed head wounds consistent with pecking.

The specimen of *A. scytale* cited here is deposited in the Museu de História Natural da Universidade Estadual de Campinas (ZUEC 02683). R. J. Sawaya gave us encouragement to submit this report; CAPES provided a grant to JPM.

Submitted by **JIVANILDO P. MIRANDA** (e-mail: jmiranda@unicamp.br) and **ANDRÉA RICCI-LOBÃO** (e-mail: andiemail@uol.com.br), Departamento de Zoologia, Instituto de Biologia, Universidade Estadual de Campinas, C.P. 6109, 13083-970, Campinas, SP, Brazil.

BOA CONSTRICTOR (Boa Constrictor). **DIET.** Boa constrictors are large-bodied snakes known to prey on a variety of lizards, birds, and mammals (Greene 1983. *In* Janzen [ed.], Costa Rican Natural History, pp. 380–383. University of Chicago Press, Chicago, Illinois). Previous accounts of avian diet items in *B. constrictor* were recently summarized in Boback et al. (2000. Herpetol. Rev. 31:244–245). Here we report an additional avian prey item. At 0735 h on 19 May 2002, an adult male *B. constrictor* (SVL 132 cm, 1.1 kg, with prey) was discovered constricting an adult female great-tailed grackle (*Quiscalus mexicanus*, Icteridae) near a resort in Placencia, Belize (Fig. 1). This snake was collected ca. 3 m above ground hanging in a dead tree and was surrounded by a flock of agitated great-tailed grackles. Ingestion of the bird, from first movement of mouth parts to storage in stomach, took 17 minutes.

FIG. 1. Male Boa constrictor in the process of swallowing an adult female great-tailed grackle near Placencia (Stann Creek District), Belize.

We thank R. N. Reed for reviewing this manuscript as well as Kitty's Place Resort for allowing us to process and store boas while in Placencia.

Submitted by **MATTHEW P. GREENE**, **SCOTT M. BOBACK**, and **CRAIG GUYER**, Department of Biological Sciences, Auburn University, Auburn, Alabama 36849, USA (e-mail [MPG]: greenmp@auburn.edu).

BOA CONSTRICTOR (Boa Constrictor). **DIET**. Recently, Bakkegard and Timm (2001. Herpetol. Rev. 32:261–262) reviewed the rodent prey reported for *Boa constrictor* and added a first record of predation on the Big-eared Climbing Rat (*Ototylomys phyllotis*; Muridae; Rodentia), from Parque Nacional Palo Verde, Guanacaste Provice, Costa Rica. In this note, we report an additional specimen of *O. phyllotis* regurgitated by a female *B. constrictor* (SVL 986 mm, TL 1013 mm), captured on 3 January 2002 in Sector San Benito of Parque Nacional El Imposible, Depto. Ahuachapán, El Salvador, 530 m elev. (13º49'N, 89º56'W). *O. phyllotis* is a common inhabitant of dry, deciduous lowland forests and dense second growth (Reid 1997. A Field Guide to the Mammals of Central America and Southeast Mexico. Oxford University Press, New York. 334 pp), habitat types that are prevalent in the Dry Tropical Forest life zone which includes both the Costa Rican and Salvadoran localities. Because these localities are situated respectively near the southern and northern limits of this particular life zone, our findings may indicate that *O. phyllotis* constitutes a regular component of *Boa constrictor* diet in this ecological assembly.

An additional female *Boa constrictor* (SVL 1145 mm, TL 1280 mm) collected on 18 February 2002, in Sector La Fincona of Parque Nacional El Imposible, Depto. Ahuachapán, El Salvador, 780 m elev. (13º50'N, 89º58'W) was found to contain a recently eaten Deppe's Squirrel (*Sciurus deppei*; Sciuridae: Rodentia) in its stomach. The snake was discovered as it crossed a dry creek bed in a forested environment, hindered in its movements by the size of the prey animal in its stomach (head-body length 210 mm, tail length 200 mm). *S. deppei* is known to be largely arboreal, but sometimes descends to the ground to feed or cross clearings (Reid 1997, *op. cit.*). Even though *B. constrictor* is semi-arboreal, it seems unlikely that the snake managed to overpower and ingest a prey animal of this size on an arboreal perch. This is the first record of a *B. constrictor* feeding on any Neotropical squirrel.

Both specimens of *B. constrictor* (YPM R12438 and YPM R12327) and the *S. deppei* (YPM 1561) are deposited in the collection of the Yale Peabody Museum of Natural History. The specimens were collected under permits from the Ministerio de Medio Ambiente y Recursos Naturales, San Salvador, El Salvador (MARN-DGPN-AIMA-8-01 and MARN-DGPN-AIMA-01-2002), and transported under CITES permit 02399. We thank James G. Owen for identifying the remains of *O. phyllotis* and confirming

the identity of *S. deppei.*

BOIGA CYANEA (Green Cat Snake) **MALE RIVALRY**. A group of adult (2.1) *Boiga cyanea* are maintained together in a display cage at West Midland Safari Park, England. A pair of the trio had produced fertile eggs resulting in viable hatchlings prior to their arrival at WMSP (Matthewson 1997. Herptile 22:113–118). On 26 August 1998, at 1830 h, the two males were observed locked in combat on the floor of the cage whilst the female was coiled on a branch above. The male rivalry consisted of both males entwining their elongate tails together in a tight and complex knot whilst their mid and anterior body sections and heads were used to compress the other to the floor in a slow twisting motion. This behavior was observed for ca. 10 min. before the males separated. The following morning the male that had previously mated the female was coiled with her on the branch whilst the second male was located under the cage floor furnishings.

Male rivalry is commonly reported for viperids, elapids, and boids, and colubrids of the genera *Elaphe*, *Lampropeltis*, and *Pituophis* (Gillingham 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 192–197. Macmillan, New York; Ford and Burghardt 1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 137–139. McGraw-Hill, New York). Shine (1978. Oecologia 33:269–277) lists male rivalry in nine non-venomous colubrid species but nocturnally arboreal, rear-fanged taxa are not represented. This appears to be a first record of male agonistic behavior, in the presence of a female, for the Asian genus *Boiga*.

Submitted by **MARK O'SHEA**, Reptile House, West Midland Safari Park, Bewdley, Worcestershire, DY12 1LF, England; e-mail: oshea@snakemos.demon.co.uk.

BOTHROPS ALTERNATUS (Urutu). **PREDATION**. *Bothrops alternatus* is a large terrestrial pitviper that occurs from central Brazil to central Argentina (Campbell and Lamar 1989. The Venomous Reptiles of Latin America, Comstock, Ithaca, New York. 425 pp.). We are unaware of any reports of predators on *B. alternatus*. We present two instances of predation and a predation attempt on *B. alternatus* by the burrowing owl, *Athene cunicularia* (Aves: Strigidae). All observations were made in Itirapina Ecological Station (IES; 22°15'S; 47°49'W, 750–780 m elev.), municipalities of Brotas and Itirapina, São Paulo State, southeastern Brazil. The *B. alternatus* and three other pitvipers (*Bothrops itapetiningae*, *B. moojeni*, and *Crotalus durissus*) are common in IES.

The first predation event occurred on 13 April 2001 at 2143 h on an unpaved road crossing an area of pristine "campo sujo" (shrubby grassland). During night driving to search for snakes we spotted a burrowing owl on the ground; when approached by the car, the owl flew away carrying a snake within its claws. After about 15 min. of unsuccessful trials, we succeeded in approaching the owl (ca. 7 m). It was on the ground, tearing small pieces (apparently only muscles and/or internal organs) off the anterior part of the snake and eating them. The snake was still showing motor reflexes, indicating that it had been attacked just before we first spotted the owl. We then drove the owl away from its prey, a young male *B. alternatus* (estimated SVL ca. 330 mm, tail 45 mm, ventrals remaining 133, estimated mass ca. 25 g). The snake's head and ca. 50–60 mm of the anterior part of the body were missing. Small portions of loose skin at the anterior end of the snake showed that the owl cut the skin middorsally and midventrally. The muscles under one of these portions of loose skin were missing (perhaps removed by the owl). There were no remains of the snake's head or neck at the site where the owl was feeding.

The second predation occurred on 26 August 2002 at 2050 h (air temperature 16°C; substrate temperature 20°C) on an unpaved road with pristine "campo limpo" (grassland) at one side and disturbed grasslands at the other. During night driving, FS spotted a burrowing owl on the ground with a snake under its claws; when we approached, the owl flew away leaving the snake on the ground. The snake (a young male *B. alternatus*; SVL 253 mm, tail 81 mm, 72.5 g) was still alive, trying to move away. The top of its head was deeply perforated (from the quadrate region to the eyes) and its left side was connected to the remains of the right side only by the anterior fourth of the head (Fig. 1). There were no additional marks on the body.

The predation attempt occurred on 2 November 2002 at 1910 h on an unpaved road crossing an area of transition beween "campo sujo" and "campo cerrado" (shrubby grassland with trees). During night driving, RJS spotted a young female *B. alternatus* (SVL 637 mm, tail 58 mm) with its body streched on the road. A burrowing owl was standing on the ground, ca. 1.5 m from the snake, staring at it. After a few minutes, the owl made two short flights (ca. 2 m each) keeping its distance from the snake, walked to a spot ca. 2.5

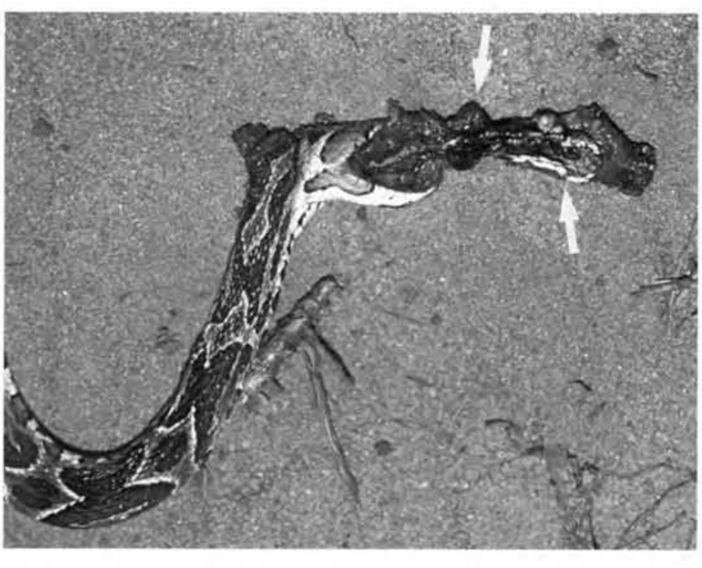

FIG. 1. Detail of the anterior part of a young male *B. alternatus* showing the wound made by a burrowing owl in Itirapina Ecological Station, southeastern Brazil. Note the lower jaw (lower white arrow) connected to the remaining body by the snout (upper arrow) region.

m from the snake, and from this spot flew towards the snake, pecked its head and landed ca. 1 m from it. Immediately after being attacked by the owl, the snake coiled its body. The owl then flew to a spot ca. 2.5 m from the snake, stayed there for 5 min., staring at the snake, and flew away (perhaps disturbed by the observer positioned ca. 10 m from the snake). When the observer approached the snake, it was hiding its head within its body coils; when approached further (about 1 m), it struck twice and hid its head again. At close examination, the snake showed a fresh small wound on the posterior part of the dorsolateral region of the head. It was then marked with a pit tag and released.

In disturbed areas in the region of São Carlos (ca. 20 km from IES), the burrowing owl feeds on insects and small vertebrates, although snake remains are very rare in pellets (four snakes out of 685 vertebrate prey; J. C. Motta-Junior, unpubl. data). However, if these owls do not eat the snake skin (as indicated by our first observation), snakes may be more frequently eaten than the examination of pellets suggest. Valdujo and Nogueira (2000. Herpetol. Rev. 31:45) reported on another species of *Bothrops* (*B. neuwiedi pauloensis*) as prey of a burrowing owl at Mineiros, Goiás, central Brazil.

Both snakes of the predation events are deposited in the Museu de História Natural, Universidade Estadual de Campinas (ZUEC 02471 and 02777, respectively). D. Zanchetta and the staff of Instituto Florestal facilitated our fieldwork at IES and J. C. Motta-Junior provided unpublished data and discussed with us the feeding habits of the burrowing owl. This is publication number 3 of the project Ecology of the Cerrados of Itirapina, funded by FAPESP.

SAWAYA** (e-mail: sawaya@unicamp.br) and **VAGNER R. ARIEDI-JUNIOR**, Departamento de Zoologia, Instituto de Biologia, Universidade Estadual de Campinas, C.P. 6109, 13083-970, Campinas, SP, Brazil.

BOTHROPS INSULARIS (Golden Lancehead). **DIET**. Accurately determining prey selection and foraging events is essential for a complete understanding of predator foraging ecology and their impact on prey communities (MacGregor and Reinert 2001. Herpetol. Rev. 32:170–172). Snakes living on small islands may have a relatively limited range of prey items available, and sometimes depend on seasonal bird migration (e.g., *Macrovipera schweizeri* [Nilson et al. 1999. Amphibia-Reptilia 20:355–375]; and *Gloydius shedaoensis* [Sun et al. 2001. Biol. Conserv. 97:387–398]).

On 20 November 2001 (1800 h) at Queimada Grande, a tiny island off the southeastern coast of Brazil (24°28'S, 46°40'W), we discovered an adult *Bothrops insularis* (ca. 60 cm total length) coiled on a freshly-killed adult Grey-fronted Dove (*Leptotila rufaxilla*) on the ground. The head and neck feathers were covered with saliva indicating that the snake had attempted to swallow the bird. Diameter at the thickest part of the bird's body was ca. 10 cm, presumably too large to be ingested by the snake. Interactions between *Bothrops insularis* and *Leptotila rufaxilla* may be common, because this bird is a frequent ground forager. A similar instance of "ingestion failure" was reported by Campos and Mello Filho (1966. A Folha Médica 52[5]:21–44).

Submitted by **MARCELO RIBEIRO DUARTE** and **PAULO SÉRGIO GARRUBO**, Lab. de Herpetologia, Instituto Butantan, Av. Vital Brazil, 1500, CEP 05503-900, São Paulo, SP, Brazil; e-mail (MRD): mrduarte@attglobal.net.

CAUSUS MACULATUS (West African Night Adder). **MALE RIVALRY**. A pair of snakes was observed in 'combat' on the grounds of a village house (expedition HQ) in the village of Bonjongo on the slopes of Mt. Etinde, in southwestern Cameroon, in February 1989. The pair was observed moving rapidly and attempting to press one another to the ground using their raised head and anterior body. There was also a considerable amount of tail-lashing. Both the snakes were presumed to be males, combating for a nearby but unseen female, since Gillingham (1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. Macmillan, New York) reports than intersexual combat behavior is rare and only observed under captive conditions.

The snakes were disturbed by the presence of the observers and they parted company to escape but one of the pair, a male, was captured and photographed. Pitman (1974. A Guide to the Snakes of Uganda, revised edition. Wheldon & Wesley, England. 290 pp.) includes Loveridge's report of fighting, biting, and neck flattening in wild male *Causus lichtensteini* and Broadley (1983. FitzSimon's Snakes of Southern Africa. Delta Books, Johannesburg. 376 pp.) reports combat in captive male *C. defilippii* and similar behavior is reported by Spawls and Branch (1995. The Dangerous Snakes of Africa. Blandford, London 192 pp.) for the same species but there seem to be no previous records of male rivalry in *C. maculatus*.

Submitted by **MARK O'SHEA**, 10 Gatcombe Way, Priorslee, Telford, Shropshire, TF2 9GZ, England; e-mail: oshea@snakemos.demon.co.uk.

CEMOPHORA COCCINEA (Scarlet Snake). **SEASONAL ACTIVITY.** In their review of the seasonal activity of *Cemophora coccinea* in Florida, USA, Enge and Sullivan (1999. Herpetol. Rev. 31:82–84) found relatively little evidence of activity during the cooler months and no records of captures during January. On 6 January 1997, I found a DOR *C. coccinea* (475 mm SVL; Milwaukee Public Museum MPM 33145) on State Highway 710 west of County Road 711, ca. 16 km W of Jupiter, Palm Beach County, Florida, USA. The weather was relatively warm; Florida cricket frogs (*Acris gryllus dorsalis*) were calling and juvenile alligators (*Alligator mississippiensis*) were active in the near vicinity. This observation is consistent with Enge and Sullivan's (*op. cit.*) speculation that *C. coccinea* may display normal low-level winter activity during warm weather.

CONOPSIS BISERIALIS (Two-lined Mexican Earth Snake). **LITTER SIZE.** On 24 March 2001, one gravid female *Conopsis biserialis* was found in a site 900 m N of Tancítaro, Michoacán, México (19°19'78.3"N, 102°22'80.2"W), 2075 m elev. The female was transported to the laboratory, housed in a container, and fed mealworm (*Tenebrio molitor*) larvae. On 16 June 2001, the female (25.7 cm SVL, 4.0 cm tail length TL) gave birth to four live neonates. Each neonate was measured and weighed. Female mass before and after parturition was 23.9 g and 16.3 g. Neonate measurements were (mean ± SD, range): 9.30 ± 0.73 cm, 8.20–10.10 cm SVL; 1.60 ± 0.30 cm, 1.20–2.0 cm TL; 1.3 ± 2.10 g, 1.3–1.3 g .

ECHINANTHERA CEPHALOSTRIATA (NCN). **DIET.** Predation on anuran eggs by Neotropical snakes is apparently widespread, although unreported for the colubrid *Echinanthera cephalostriata*. In November 1991 we received an adult male *E. cephalostriata* (540 mm total length) from Marmeleiro, Almirante Tamandaré Municipality, Paraná State, Brazil, now housed in the Museu de História Natural Capão da Imbuia herpetological collection (MHNCI 4690). We examined stomach contents and found 32 intact frog eggs, appearing to have just been ingested and at an early developmental stage. The eggs were identified as belonging to the leptodactylid genus *Eleutherodactylus* (probably *E. guentheri*, the only species of this genus known for this locality, and like other species in the genus it lays terrestrial eggs which undergo direct development).

Snake identification was verified by Marcos Di-Bernardo, and the *Eleutherodactylus* eggs by Magno Vicente Segalla.

ELAPHE OBSOLETA SPILOIDES (Gray Ratsnake). **FEEDING.** Food of *Elaphe obsoleta*, includes largely birds, bird eggs, and mammals, with the latter predominating in studies from Kansas (Fitch 1963. Copeia 1963:649–658) and Maryland (Stickel et al. 1980. Am. Midl. Nat. 103:1–14). The southern subspecies may be highly arboreal in its pursuit of these prey (Jackson 1974. Auk 91:342–347).

Large snake species like those in the genus *Elaphe* may take only a few large meals during a year (Mushinsky 1987. *In* Seigel et al. [eds.], Snakes. Ecology and Evolutionary Biology, pp. 302–334. Macmillan Publ., New York, New York) making field observations of these rare events less likely. One of us (DL) observed a feeding event between a large adult *E. o. spiloides* and an adult gray squirrel (*Sciurus carolinensis*) in mid-May 2001 at ca. 1600 h at Melton Bottom, ca. 15 km ESE West Point, Clay County, Mississippi, USA. The snake, estimated at > 2 m total length, and squirrel fell to the ground simultaneously but not entwined, from a height of ca. 10 m in an oak tree. DL retrieved a camera and took 14 photographs as the snake constricted and consumed the squirrel.

The squirrel was still living but appeared stunned after falling. It may have already been attacked and constricted in the tree. Constriction (Fig. 1) appeared typical for snakes of the genus *Elaphe* as illustrated and described by Willard (1977. Copeia 1977:379–382). Following the terminology of Greene and Burghardt (1978. Science 200:74–77), the constriction shown in Fig. 1 involved a winding application movement, snake's belly away from its head, posterior coil composition, and long axis of coil horizontal to substrate. Complete headfirst consumption of the squirrel took ca. one hour during which time the snake was no longer coiled around the squirrel.

FIG. 1. Feeding constriction of a gray squirrel by an adult gray ratsnake (*Elaphe obsoleta spiloides*) in Mississippi. The snake's head, with one eye and extended tongue, is visible just to the right of the squirrel's head.

Submitted by **DAVID LOTT**, 2624 Curtis Orman Road, West Point, Mississippi 39773, USA, and **WILLIAM S. PARKER**, Division of Science and Mathematics, Mississippi University for Women, Columbus, Mississippi 39701, USA (e-mail: bparker@muw.edu).

LAMPROPELTIS CALLIGASTER CALLIGASTER (Prairie Kingsnake). **PIGMENTATION**. In early October 1988, a leucistic juvenile male *Lampropeltis c. calligaster* was discovered DOR by Patricia Pisani within the city limits of Lawrence (Douglas County) Kansas, USA. It was preserved by GRP, and is in the KUMNH collection (KU 291545). There exists the possibility that the animal was albino, though condition of the specimen precluded precise determination. Albinism in *L. c. calligaster* was summarized by Dyrkacz (1981. SSAR Herpetol. Circ. No. 11:1–32). Overall pigmentation is white, with faintly discernible pattern typical of the species.

Sincere thanks are expressed to Patricia Pisani for collecting the snake.

Submitted by **GEORGE R. PISANI**, Research Associate, University of Kansas Field Station and Ecological Reserves, 350 Wild Horse Road, Lawrence, Kansas 66044, USA; e-mail: gpisani@ku.edu.

LAMPROPELTIS TRIANGULUM (Milk Snake). **HABITAT.** Habitat associations of the milk snake in the western United States are poorly understood. In the eastern Great Basin and in the northern Colorado Plateau, accounts typically state that *Lampropeltis triangulum* is found in forests, grasslands, and riparian zones, especially in relatively mesic montane valleys and foothills (e.g., Cox and Tanner 1995. Snakes of Utah. Brigham Young University, Provo, Utah. 92 pp.; Hammerson 1999. Amphibians and Reptiles in Colorado. University Press of Colorado, Niwot, Colorado. 484 pp.; Williams 1988. Systematics and Natural History of the American Milk Snake. Milwaukee Public Museum, Milwaukee, Wisconsin. 176 pp.). Recent observations, and a re-evaluation of previously reported collection localities, indicate that *L. triangulum* inhabits a broader spectrum of habitats. One of us (KWS) observed a *L. triangulum* in arid, big sagebrush (*Artemisia tridentata*) dominated shrubland along the foothills of the Stansbury Mountains, Tooele Co., Utah, USA, in the eastern Great Basin. Surface water was not present within several miles. The presence of *L. triangulum* in arid sagebrush shrubland in the eastern Great Basin is further supported by additional specimens from nearby localities (BYU 334, USNM 335572), from literature reports from another site in the Stansbury Mountain foothills (Brown and Parker 1982. *In* Scott [ed.], Herpetological Communities, pp. 59–81. U.S. Fish and Wildlife Service, Wildlife Research Report No. 13), and from a specimen from similar habitat south of the Stansbury Mountains (BYU 8922).

Two of us (DGM and BLW) also encountered two specimens of *L. triangulum* in arid, sparsely vegetated, greasewood (*Sarcobatus*), sage (*Artemisia*), and shadscale (*Atriplex*) shrubland habitats in the northern Colorado Plateau, Carbon Co., Utah, USA. Surface water was not present near either location. Both observations of *L. triangulum* from the Colorado Plateau were from broad, desert flats of the upper Price River drainage. Shaded range maps provided by Cox and Tanner (*op. cit.*) erroneously indicate that *L. triangulum* occurs only in montane regions of the Wasatch Plateau and the Book Cliffs in this region. The presence of *L. triangulum* in arid shrubland habitats in the northern Colorado Plateau is supported by several museum specimens (BYU 2933, BYU 30531, LACM 102472–3, UTEP 9593). Records of *L. triangulum* on the Colorado Plateau south of the Colorado River are also from arid habitats far from sources of permanent water (Fowlie 1965. The Snakes of Arizona. Azul Quinta Press, Fallbrook, California. 164 pp.; Holycross and Simonson 1998. Herpetol. Rev. 29:113–114; Erika Nowak, pers. comm.). However, all of these southern specimens are from grassland habitats. None of the *L. triangulum* we observed was found in an area with a substantial grassy component. These observations indicate that *L. triangulum* in the western United States occupies a wider variety of habitats than is typically recorded, and might be more widely distributed than is currently known.

Submitted by **KIRK W. SETSER** (e-mail: setser@biology.usu.edu), **DANIEL G. MULCAHY** (e-mail: dmulcahy@biology.usu.edu), and **BECKY L. WILLIAMS** (e-mail: beckyw@biology.usu.edu), Department of Biology, Utah State University, Logan, Utah 84322-5305, USA.

LAMPROPELTIS ZONATA (California Mountain Kingsnake). **DIET**. *Lampropeltis zonata* is an inhabitant of mesic, well lit, rocky canyons and moist woodlands. Its diet (reviewed in Zweifel 1974. Cat. Am. Amphib. Rept. 174.1–174.4; McGurty 1988. Proc. Conf. California Herpetol. 73–78; Cranston 1994. Vivarium 6[3]38–43,47) consists of squamates and their eggs, mammals, and birds. Documentation of *L. zonata* predation on lizards includes skinks (*Eumeces*) and spiny lizards (*Sceloporus*). Here we report the first evidence for predation on an alligator lizard (*Elgaria*). This report is also significant because of the relatively large size of the food item.

While conducting biotic field surveys in Sequoia National Forest (USA: California: Kern Co.) we collected a subadult, male *L. zonata* (295 mm SVL, 11.5 g) at Alder Creek, Greenhorn Mountains (35°43'6.5"N, 118°35'48.2"W). The snake was found on 18 June (~1500 h), under a rock 5 m from the creek. The body of the *L. zonata* was visibly distended. Regurgitation of the food item was induced by palpation. The food item was revealed to be a southern alligator lizard (*Elgaria multicarinata*; 79 mm estimated SVL, 7.1 g) that was swallowed head first. The mass of the partially digested *E. multicarinata* was 61.7% of the mass of the *L. zonata*. The *L. zonata* and *E. multicarinata* were deposited in the California Academy of Sciences (CAS 223955).

We thank Michelle Koo, Jens Vindum, and Phillip Strand for their supervision during this field work which was funded by Challenge Cost-Share Agreement #00-CC-11051322-034, Forest Service Region 5, Sequoia National Forest.

Submitted by **JAMES FORD PARHAM**, Department of Integrative Biology, University of California, Berkeley, California 94720-3140, USA (e-mail: parham@socrates.berkeley.edu), and **CHRIS R. FELDMAN**, Department Biology, Utah State University, Logan, Utah 84322-5305, USA.

MASTICOPHIS FLAGELLUM CINGULUM (Sonoran Coachwhip). **DEFENSIVE BEHAVIOR.** *Masticophis flagellum* exhibits a suite of defensive behaviors when threatened or handled, including mouth gaping, hiding the head under the body, hissing, holding the trunk limp, and vibrating the tail (reviewed by

Carpenter and Ferguson 1977. *In* Gans and Tinkle [eds.], Biology of the Reptilia, Vol. 7, Ecology and Behavior, pp. 335–554. Academic Press, New York, New York). Recent observations document death feigning by coachwhips in Oklahoma (Tucker 1989. Herpetol. Rev. 20:72) and Arizona (Repp 2001. Sonoran Herpetol. 14:130–131). Here I document a defensive behavior previously unreported for this species.

On 21 July 2001 at ca. 1030 h, I captured a juvenile *M. f. cingulum* (ca. 30 cm SVL) from under debris near Tucson, Arizona, USA (32°08'N, 110°41'W). It had rained < 0.1 cm earlier in the day and was unseasonably cool (30°C at 1 m above ground). The snake was somewhat active in hand but made no attempt to bite; therefore, I held the snake loosely without restraining it behind the head. The snake did not defecate. While positioning the snake for photography, it assumed a "snout down-neck up" posture. The snout was positioned greater than 45° to the ground, pushed into the substrate, and the snake's neck was raised and arched. The snake periodically made tentative attempts to crawl away but was easily recaptured and repeatedly assumed the position described. The snake continued this behavior for 12–15 min. while being photographed.

This behavior has been reported for several snakes including elapids, viperids, and colubrids (e.g., *Pituophis catenifer* and *Elaphe* spp.) (see Carpenter and Ferguson 1977, *op. cit.*), although its function is unclear.

Submitted by **ERIC W. STITT**, School of Renewable Natural Resources, 125 Biological Sciences East, University of Arizona, Tucson, Arizona, 85721, USA; e-mail: estitt@u.arizona.edu.

MICRURUS ALTIROSTRIS (Southern Coral Snake). **DIET**. The diet of South American coral snakes includes amphisbaenians, lizards, snakes, caecilians, fishes and invertebrates (Procter 1923. Proc. Zool. Soc. 192:1061–1067; Dixon and Soini 1977. The Reptiles of the Upper Amazon Basin, Iquitos Region, Peru II: Crocodilians, Turtles and Snakes. Milwaukee Publ. Mus. 91 pp.; Vanzolini 1986. Levantamento Herpetológico na área do Estado de Rondônia sob a Influência da Rodovia BR 364, Relatório de Pesquisa 1, Brasília: CNPq, Assessoria Editorial 50 pp.; Cunha and Nascimento 1993. Bol. Mus. Par. Emílio Goeldi 9:1–191; Jorge da Silva 1993. Herpetol. Nat. Hist. 1:37–86; Marques and Sazima 1997. Herpetol. Nat. Hist. 5:88–91). *Micrurus altirostris* feeds on amphisbaenians of the genus *Amphisbaena* and snakes of the genera *Atractus*, *Liophis,* and *Sibynomorphus* (Jorge da Silva 1995. Molecular Systematics and Evolution of Venoms in the South American "Triad" Coral Snakes (*Micrurus,* Elapidae). Ph.D. dissertation. Brigham Young Univ. Provo. 226 pp.). However the data available are not sufficient to determine the species of amphisbenids involved, owing to the degree of preservation of the specimens found in stomach contents (Jorge da Silva and Aird 2001. Comp. Biochem. Physiol. Part C 128:425–456).

On 14 January 2000, we collected on the eastern bank of Uruguai River (27°22'42"S, 51°28'58"W) a specimen of *M. altirostris,* near Itá, Santa Catarina, Brazil (Centro de Estudos e Pesquisas Biológicas, Goiânia, Goiás - CEPB/RSR 016, SVL 529 mm) that contained a specimen of *Amphisbaena prunicolor* (169.7 mm TL). The head of the *A. prunicolor* was completely digested. This is the first record of *M. altirostris* feeding on amphisbenids identified to the specific level and it might help to better our knowledge of the biology of this species of Southern Brazil.

NERODIA ERYTHROGASTER FLAVIGASTER (Yellow-bellied Water Snake). **MATING AGGREGATION.** I observed a mating aggregation of water snakes (*Nerodia erythrogaster flavigaster*) below a bridge in a small seasonal stream in my suburban neighborhood in West Point, Clay County, Mississippi, USA (33°35'14"N, 88°37'46"W). Observations were made between 1015 and 1100 h on 28 April 2001, air temperature ca. 21°C; water depth ca. 0.5 m, clear and flowing; location in direct sunlight; stream < 5 m wide. I was on a bridge ca. 6–7 m above and 3–4 m horizontally away from a group of 3–4 large cement blocks, each ca. 1–1.5 m^2 and 0.5 m thick. I have walked across this bridge on foot hundreds of times per year for the last 15–20 yr and previously have seen only one snake at this location.

Initially, I observed one adult snake emerging from beneath one of the blocks onto the sloping surface of another block as if to bask. In a few moments, a smaller individual emerged and began gliding over the back of the first individual, crawling first toward its head, then toward its tail. Another large individual emerged into the water on the other side of this same block, followed quickly by another smaller individual. This second larger individual remained rather motionless and seemingly passive in the water while the second individual maneuvered alongside. In fairly rapid succession, three smaller individuals emerged from under the block and moved alongside the first individual, such that the five snakes were aligned in an undulating fashion. The tails of some of them were intertwined and I could see the plain yellow bellies of some of the snakes as their tails and lower bodies twisted together. Heads

FIG. 1. Mating aggregation of five or six yellow-bellied water snakes (*Nerodia erythrogaster flavigaster*) in West Point, Mississippi, USA. Intertwined tails of five individuals are visible to the left and heads of four individuals scattered upper center and upper right.

of all five snakes were also visible and exhibited no obvious interactions such as pushing or biting. At this point, I left to get a camera and was gone for ca. 20 min.

When I returned, I observed an aggregation of snakes on the flattest part of a different block in the center of the stream (Fig. 1) and took a series of six photographs. Some photos show five heads and the rear parts and tails of five bodies aligned in plain view on top of the cement block. The snakes separated as I took the last photo and there was no evidence that there had been successful intromission as would have been evidenced by two of the snakes staying connected. Because the two larger individuals (est. length 1 m) appeared passive and sedentary and had larger heads, I assumed that they were females and that the five smaller individuals (est. length 0.6–0.75 m) were all males.

Mating in *N. erythrogaster* has been noted from April to June in different parts of its range (Diener 1957. Herpetologica 13:203–211, Arkansas; Wright and Wright 1957. Handbook of Snakes, Comstock Publ., Vol. I, 564 pp., Illinois and Michigan; Preston 1970. The Comparative Ecology of Two Water Snakes, *Natrix rhombifera* and *Natrix erythrogaster*, in Oklahoma. Ph.D. dissertation. Univ. of Oklahoma, Oklahoma. 79 pp.). Mating aggregations have been reported in *N. sipedon* (Tinkle and Liner 1955. Field and Lab. 23: 84–87; Mushinsky 1979. J. Herpetol. 13:127–129) but I found no studies describing mating groups of *N. erythrogaster*.

Submitted by **WILLIAM S. PARKER**, Division of Science and Mathematics, Mississippi University for Women, Columbus, Mississippi 39701, USA; e-mail: bparker@muw.edu.

OXYBELIS FULGIDUS (Green Vine Snake). **PREY**. *Oxybelis fulgidus* is a large opistoglyphous colubrid snake that is known to prey on anoles (genus *Norops*) and other lizards, but also on frogs, small mammals, birds, and insects (Köhler 2001. Reptilien und Amphibien Mittelamerikas. Band 2: Schlangen. Herpeton Verlag, Offenbach, Germany. 174 pp)..

During a recent study of the herpetofauna and avifauna of El Salvador, an adult male *Oxybelis fulgidus* (SVL 1285 mm, TL 1972 mm) was found tangled in a mistnet, attempting to eat an adult Ruddy Woodcreeper (*Dendrocincla homochroa*; Dendrocolaptidae; Passeriformes) that was caught in the net earlier. The snake was discovered at 1600 h on 17 February 2002, in a 20-year old patch of secondary vegetation in Sector La Fincona of Parque Nacional El Imposible, Depto. Ahuachapán, El Salvador, at 750 m elev. (13°50'N, 89°58'W), as it held the head and neck of the *D. homochroa* in its mouth and with several strands of the net's mesh wrapped around its head and caught on its temporal and nuchal scales. The snake was unable to release the bird or extricate itself. Examination of the bird revealed several puncture marks on the left scapular region and upper wing, which corresponded with the width of the snake's mouth, presumably from the initial bite and the subsequent "chewing" for injecting the immobilizing Duvernoy's gland secretion.

The *D. homochroa* entered the net ca. 25 cm above the ground, but weighed down the net sufficiently so that its body almost touched the forest floor. *O. fulgidus* hunts for both terrestrial and arboreal prey, but invariably from an arboreal perch (Henderson and Nickerson 1975. Brit. J. Herpetol. 5:663–667). Because the net was placed in a roughly 2 m-wide lane cleared of vegetation and adjacent branches, the snake could only approach the bird over the ground, making this the first record of *O. fulgidus* descending to the ground to hunt.

These snakes seem incapable of visually locating prey that remains immobile (Henderson and Nickerson 1975, *op. cit.*). The movements of the netted bird must have been sufficient to draw the snake's attention and entice it to descend from a nearby perch and cross the ca. 1.5 m wide cleared net lane from the closest vegetation.

Both the *Oxybelis fulgidus* and the *Dendrocincla homochroa* are deposited in the collection of the Yale Peabody Museum of Natural History (YPM 12348 and YPM F2835, respectively). The specimens were collected under permits from the Ministerio de Medio Ambiente y Recursos Naturales, San Salvador, El Salvador (MARN-DGPN-AIMA-8-01, MARN-DGPN-AIMA-11-1, and MARN-DGPN-AIMA-01-2002). We thank Oliver Komar for confirming the identification of the bird.

Submitted by **TWAN A.A.M. LEENDERS** (e-mail: twanleenders@scinax.com) and **GREGORY J. WATKINS-COLWELL** (e-mail: gregory.watkins-colwell@yale.edu), Division of Vertebrate Zoology, Yale Peabody Museum of Natural History, 170 Whitney Avenue, P.O. OXYRHOPUS RHOMBIFER (False Coral Snake). **PREDATION**. *Oxyrhopus rhombifer*, a medium-sized colubrid with a coral snake color pattern, occurs from the Amazon River south to central Argentina (Peters and Orejas-Miranda. 1986. Catalogue of Neotropical Squamata. Smithsonian Institution Press, Washington, D.C., 347 pp.). We are unaware of any published accounts of predation on *O. rhombifer*. Here we report an instance of predation by the Burrowing Owl, *Athene cunicularia* (Aves: Strigidae). The observation occurred on 26 May 2001 at 2145 h on an unpaved road crossing an area of pristine "campo sujo" (shrubby grassland of the cerrado, savanna-like formation; 22°12'30"S, 47°54'45"W, 760 m elev.) at Itirapina Ecological Station (IES), municipality of Brotas, São Paulo State, southeastern Brazil. During night driving to search for snakes we spotted a Burrowing Owl on the ground; when approached by the car, the owl flew away carrying a snake within its claws; the owl landed ca. 50 m from the site where we first saw it, quickly got into the grassland, and flew away again. We searched the area and found its prey at roadside. . It was an adult male *O. rhombifer* (estimated SVL ca. 420 mm, tail with tip lacking, probably removed by the owl, 104 mm, estimated mass ca. 24 g). The anterior 190 mm of the body was missing, and injuries were evident in the cloacal region and at midbody.

Martins et al. (2003. Herpetol. Rev. 34:147–148) reported on a *Bothrops alternatus* as prey of a Burrowing Owl at IES and suggested that snakes may be more frequently eaten than the examination of owl pellets suggests. Valdujo and Nogueira (2000. Herpetol. Rev. 31:45) reported on a *B. neuwiedi pauloensis* as prey of a Burrowing Owl in another area of cerrado at Mineiros, Goiás state, central Brazil.

The voucher specimen of *O. rhombifer* is deposited in the Museu de História Natural, Universidade Estadual de Campinas (ZUEC

02476). D. Zanchetta and the staff of Instituto Florestal allowed and facilitated our fieldwork at IES. FAPESP provided a grant to RJS (99/05664-5). We thank M. Martins for suggestions on the manuscript. This is publication number 5 of the project Ecology of the Cerrados of Itirapina.

PHALOTRIS PUNCTATUS (NCN). **OVIPOSITION.** Very little is know about the life history and ecology of *Phalotris punctatus* (Cei 1993. Reptiles del Noroeste, Nordeste y Este de Argentina; Herpetofauna de las Selvas Subtropicales, Puna y Pampas. Mus. reg. Sc. nat. Torino, Monogr. 14:1–949). I report on a clutch from a specimen captured in a xeric forest of the Chaco region in Argentina (Biological Station Los Colorados; 24°41'S, 63°18'W; Salta, Argentina). A gravid female of *P. punctatus* (365 mm SVL, 20 mm tail length) was collected at 0800 h on 1 December 1995 on a road and subsequently kept in captivity. Six days later this female laid two eggs (32.2 mm x 7.7 mm and 30.2 mm x 7.6 mm). The eggs were incubated in the laboratory, but did not hatch.

Upon death of this specimen, I dissected it to expose reproductive organs and determined the absence of oviduct eggs or vitellogenic follicles. The specimen was added to the snake collection of the Centro de Zoología Aplicada (Universidad Nacional de Córdoba) (CZA n° 120). This is the first report on clutch size in *P. punctatus*.

Submitted by **GERARDO C. LEYNAUD**, Centro de Zoología Aplicada (Serpentario), Universidad Nacional de Córdoba. Rondeau 798, Casilla de Correo 122. Córdoba (5000) Argentina; e-mail: gleyanud@gtwing.efn.uncor.edu.

PHILODRYAS BARONI (Green Snake). **COURTSHIP BEHAVIOR**. Here, we report the courtship behavior of a neotropical snake, *Philodryas baroni*, from northwestern Argentina. Little is known about this behavioral aspect of the species except for what has been reported by Williams (1984. La Culebra Verde. Fauna Argentina, Centro Editor de América Latina, Buenos Aires, 48:1–32). From 9 to 25 August 2000, we observed courtship in a captive male and female *P. baroni*. The male had been in captivity for 3 months prior to observations. On 9 August 2000 a freshly caught female was placed in the male's terrarium (70 x 50 x 50 cm). The male immediately showed interest in the female, tongue-flicking her, especially the anterior third of her body, and following her around the terrarium. Soon, the male positioned himself on the female and typical colubrid courtship behavior ensued. The male performed chin rubbing followed by body undulations and dorsal advances and retreats (e.g., Carpenter 1977. Amer. Zool. 17:217–223; Gillingham 1987. *In* R. A. Seigel, J. T. Collins and S. S. Novak [eds.], Snakes: Ecology and Evolutionary Biology, MacMillan Publishing Co., New York, pp. 184–209). Chin rubbing consisted of a slight quivering motion of the male's head over the nuchal area of the female. This was followed by a series of 1–5 cephalocaudal waves. Meanwhile, the female remained passive. What was unusual was that the male continued this behavior for the following 14 days. During this time, human interventions were avoided and the snakes were not fed. We visually checked on them every day, mornings and afternoons, always finding the male on top of the female doing occasional chin rubbing and body undulations. We filmed the courtship behavior for a total of 9 h on 5 different days. We found that wave sequences occurred, on average, every 15 min by the third day that the pair had been placed together, increasing to one sequence every 4 min by the ninth and tenth day, and finally slowing down to one every 12 min on the fourteenth day. By the fifteenth day, the male and female were found coiled in different corners of the terrarium. The male showed no further interest. Video analyses show occasional cloaca juxtaposition, in particular by the end of the first week. Although captivity may be a factor, GS observed in a field situation (Bañado de Figueroa, Santiago del Estero province) a male that remained with a female for more than 3 days. We suggest that the male may stay with the female for so long in order to prevent access of other males while the female is still receptive (Gillingham, *op. cit.*) and thus ensure paternity. The pair died a few months later, possibly of a parasite infection (FML 08922 and 10367).

PHILODRYAS PATAGONIENSIS (NCN). **DIET**. *Philodryas patagoniensis* is a generalist predator known to feed on anurans, lizards, snakes, small mammals, and birds (Achaval and Olmos 1997. Anfibios y Reptiles del Uruguay. Montevideo, Uruguay, 128 pp.; Amaral 1978. Serpentes do Brasil - Iconografia Colorida, 246 pp.; Carvalho-Silva and Barros-Filho 1999. Herpetol. Rev. 30:170; Gonzaga et al. 1997. Herpetol. Rev. 28:154; Lema et al. 1983. Com. Mus. Ci. PUC-RS. Contribuição ao conhecimento da alimentação e do modo alimentar de serpentes do Brasil, pp. 41–121; Marques et al. 2000. Serpentes da Mata Atlântica Guia Ilustrado para a Serra do Mar. Editora Holos, 184 pp.; Rocha and Vrcibradic 1998. Ciência e Cultura 50[5]:364–368). In this note we report a new prey species for *P. patagoniensis*, a bird of the genus *Turdus*.

An adult male *P. patagoniensis*, with an obvious mid-body bulge, was found in Dom Feliciano Municipality, Rio Grande do Sul State (30°25'23.5"S, 52°18'41.4"W) by RLB on 20 January 2001. The snake was basking on the ground at ca. 1100 h in an open area of high grassland.. Upon dissection, a sub-adult *Turdus* sp. (sabiá) was found in its stomach, having been ingested headfirst.

PHILODRYAS PATAGONIENSIS (Papa-pinto). **CANNIBALISM.** Cannibalism is known to occur in a number of species of snakes, whether they are customarily ophiophagous or not. *Philodryas patagoniensis* is a terrestrial and diurnal colubrid snake that feeds on small vertebrates such as anurans, lizards, birds, rodents, and snakes (Lema et al. 1983. Comun. Mus. Ci. PUC-RS 26:41–121; Vanzolini 1948. Rev. Bras. Biol. 8:308–311; Yanosky et al. 1996. Herpetol. Nat. Hist. 4:97–110; Di-Bernardo 1998. História natural de uma comunidade de serpentes da borda oriental do Planalto das Araucárias, Rio Grande do Sul, Brasil. Tese de doutorado. Universidade Estadual Paulista, Rio Claro. 119 pp.). Lema (*op. cit.*) recorded two cases of cannibalism in *Philodryas patagoniensis*, one observed in captivity, and another under natural conditions. In the latter, a juvenile regurgitated a conspecific juvenile after being captured. Here we register two cases of cannibalism in *P. patagoniensis*. One was observed directly in an area of sand dunes located in the municipality of Balneário Pinhal (30°18'00"S, 50°15'53"W) in the coastal plain of Rio Grande do Sul, Brazil, and the other was recorded after dissection of a preserved specimen.

At 1045 h on 1 February 2001 we found an adult female *Philodryas patagoniensis* (840 mm SVL) coiled around a smaller conspecific female (578 mm SVL). The anterior portion of the snake had been already ingested. When we approached, the larger individual released its prey and tried to flee, and was then captured. The prey snake was dead and was deposited in the collection of the Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul (MCP 12184); the larger snake was measured and released at the place of capture.

Upon dissection, a preserved gravid female *Philodryas patagoniensis* (MCP 5638; 1068 mm SVL), from the municipality of Cachoeira do Sul (30°02'S, 52°54'W), Rio Grande do Sul, contained an adult male conspecific (500 mm SVL) and one lagomorph of the family Leporidae.

With the incidents of cannibalism reported here, and those reported previously, we suggest that *P. patagoniensis* does not discriminate between conspecifics and other prey items.

We thank John Measey and Robert A. Thomas for useful comments on earlier versions of this manuscript, and Julio César González for the identification of the lagomorph. One of us (RBO) benefited from a graduate fellowship from Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES).

PITUOPHIS CATENIFER CATENIFER (Pacific Gophersnake). **PREY SIZE.** On 9 September 1999 at 1400 h I found a dead juvenile *Pituophis catenifer catenifer* (298 mm SVL) floating in a small stream at Concord Naval Weapons Station, Concord, California, USA (38°00'N, 121°59'W). The snake had apparently been dead less than 12 h as the skin was still intact and firm, there was no evidence of predation by aquatic scavengers (e.g., crayfish [*Procambarus* sp.]), and the coloration of the pattern was life-like. The snake's stomach was noticeably distended.

I weighed the dead snake and removed the prey item from the stomach. Very little digestion had taken place and the prey item was readily identified as a male house mouse (*Mus musculus*), 76.0 mm in body length. The mouse had been swallowed head-first. The wet mass of the snake was 12.2 g and the wet mass of the mouse was 11.5 g; 94.3% of the snake's body weight. No other food items were present in the stomach.

Such large prey items are not unknown (see references in Greene 1997. Snakes: The Evolution of Mystery in Nature; University of California Press, Berkeley, California, 351 pp.), and may occasionally cause mortality (Godley 1980. Ecol. Monogr. 50:411–436) or injury (Pauley and Benard 2002. Herpetol. Rev. 33:56–57). In this case, the cause of death is unknown. The evidence suggests, however, that the snake may have drowned due to compromised mobility.

PSEUDOBOA HAASI (NCN). **PREDATION.** Predation on Neotropical snakes from the southern Brazilian araucarian forest region is poorly documented. On 9 August 2001, one of us (CS) observed a *Rupornis magnirostris* (Aves: Accipitridae), a diurnal predator, attacking an adult *Pseudoboa haasi* (128.5 cm total length) in an open, altered area adjacent to araucarian forest near Rio Negrinho Municipality, State of Santa Catarina, Brazil. The bird took flight upon being disturbed. The snake was deposited in the herpetological collection of Museu de História Natural Capão da Imbuia at Curitiba, Paraná State (MHNCI10315). This is the first record of predation for *P. haasi*. The genus *Pseudoboa* is primarily nocturnal (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:120–121), and *P. haasi* is an endemic species from the araucarian forest domain of southern Brazil, the coldest ecosystem of the country (Morato et al. 1995. Biociências 3[2]:253–264). Our report indicates that this species is at least occasionally diurnal. We thank Renato Silveira Bérnils for verifiying the snake's identity, and Eduardo Ramires for the revision of the English version.

PSEUDONAJA TEXTILIS (Eastern Brown Snake) **FAILED PREDATION.** Reports of failed attempts at predation by snakes as a result of trying to ingest unmanageable prey exist (Arnold 1993 *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 87–115. McGraw Hill, New York; Shine 1993. Australian Snakes: A Natural History. Reed Books Pty Ltd, Sydney, 223 pp.; Gavin Bedford, pers. comm.). Such episodes provide insights into predator capabilities and anti-predator behaviors of prey. Here, I add to these data with the observation of an attempt by an eastern brown snake, *Pseudonaja* textilis, to prey on an eastern bearded dragon, *Pogona barbata*. I made the observation in the course of a telemetry study of *P. barbata* throughout remnant vegetation along roadsides surrounded by agricultural land near the town of Bendigo in the state of Victoria, Australia (36°27'42"S; 143°45'10"E).

At 0730 h on 18 November 1999, while radiotracking a female *P. barbata* (23.6 cm SVL), I noticed a ca. 1.5-m *P. textilis* to my right, coming around the base of a large (1.5 m DBH) Grey Box tree (*Eucalyptus microcarpa*). The snake was moving across my field of view, heading in the direction of my radio signal. The *P. barbata* was perched on a relatively thin (> 5 cm diam) branch ~15 cm above the ground. The female was facing away from me at a distance of ~2 m, but had the antenna of the transmitter (attached to the base of the tail) pointed towards me. The snake lifted its head above the ground and seemed distracted, enough so that it appeared not to notice me. As it continued to move forward slowly, it rapidly jerked its head from side to side constantly flicking its tongue.

The dragon seemed aware of the snake, as it was trying to peer backwards while moving its body as little as possible. Suddenly, the snake lifted its head and its tongue flicked the radio-transmitter. It then slowly opened its mouth and grabbed the right rear thigh of the dragon. The dragon simultaneously arched its head back, opened its mouth, puffed out its beard, then let go of the branch. This caused the snake to lose its grip and the dragon ran towards a wire fence ~1 m away. The snake moved after it quickly, raising about one third of its body off the ground. The dragon appeared to have been momentarily stuck in the mesh of the fence and by the time I had taken the few steps to peer over it, the snake had the dragon's snout in its mouth and had wrapped several coils around its body.

The snake used more than one method in attempting to engulf the large dragon. Initially, it tried to walk its jaws over the dragon's head (Fig. 1). After about 10 minutes, it then wrapped several coils around the animal's body and seemed to be trying to push the dragon into its mouth. Failing this, the snake then uncoiled fully and tried to pull the dragon through the grass, possibly aimed at stretching the animal out to aid its ingestion (Valderrama 2001. Herpetol. Rev. 32:46–47).

Despite moving relatively little and pale in color, the dragon actively pushed its beard outward. Every time the snake loosened its grip to change position, the dragon would quickly suck in air and inflate itself even more. Eventually it appeared distended, as captured wild individuals sometimes appear in the hand (J. Smith, unpubl. data).

FIG. 1. Adult eastern brown snake (*Pseudonaja textilis*) attempting to ingest an adult female eastern bearded dragon (*Pogona barbata*).

About 40 minutes after the initial attack, the snake let go and moved off. Only when I stood up to watch its departure did the snake appear to notice me, inflating its throat slightly and increasing its speed in the opposite direction. The dragon did not move at all in the ensuing minutes and its body retained the same pale color. There were scattered blood spots on top of its head. When I returned at 1100 h, the dragon had moved under a large log nearby that it had frequented previously. Subsequent tracking during the following weeks gave no indication of a change in the behavior of this dragon, and she eventually became gravid.

None of the adult dragons (6 females, 3 males) that I telemetered during this study were killed by snakes. *Pseudonaja textilis* is known to consume juvenile *P. barbata* (Oliver 1998. Herpetofauna 28:54); however, the width of this dragon's head, including the inflated beard, presented a very large prey item for even an adult *P. textilis* to consume. The residual blood seen on the dragon's head may have been left by the snake. I did not see an obvious bite on the dragon but the snake may have broken some teeth off as I could hear them scraping over the dragon's head. If the blood was from the dragon (and assuming the snake injected any venom), this poses interesting questions about the potency of brown snake venom on eastern bearded dragons. Nevertheless, some defense mechanisms of adult *P. barbata* appear sufficient to repel a major predator. Conversely, episodes such as this one may also occur because snakes attempt ingestion when the large size of prey is unrecognized.

SISTRURUS CATENATUS CATENATUS (Eastern Massasauga). **MALE-MALE AGGRESSION**. Selection for traits that confer a mating advantage (e.g., bright plumages, elaborate ornaments, large body size) can occur through female choice and/or male-male competition (Darwin 1871. The Descent of Man, and Selection in Relation to Sex. Murray, London. 898 pp.). In many species, competition for mates results in aggressive interactions between members of the same sex, usually males. Aggressive behavior has been previously reported for many species of pitvipers in which

males engage in ritualized combat (see Carpenter 1986. Smithsonian Herpetol. Inform. Serv. 69:1–18). Within the genus *Sistrurus*, male aggressive behavior has been observed in captive *S. miliarius* (Carpenter 1979. Copeia 1979:638–642) and *S. ravus* (Armstrong and Murphy 1979. Univ. Kansas Mus. Nat. Hist., Special Publ. 5:1–88). Although male-male aggressive interactions are suspected to occur in *S. catenatus*, they have not been substantiated.

On 20 August 2001 at 1255 h, while radio-tracking a male *S. c. catenatus* at Eldon Hazlet State Park, Clinton County, Illinois, USA, we noticed some aberrant behavior. The snake (#186) was moving through the vegetation while rapidly tongue flicking and probing the ground cover with his head. We followed the snake for ca. 4 m where he encountered a copulating pair of *S. c. catenatus*. The pair was straightened out, but facing opposite directions. Male #186 moved over the pair to an outstretched position on top of the male (#245). Male #186 then elevated the anterior portion of his body vertically, forming an S-shape, and laterally undulated. Male #245 remained still except for hitting male #186 with his thrashing tail. Male #186 continued his elevated body undulations then moved around toward the female resulting in a looped position on top of the male. Male #245 then moved his head to a position above male #186 at mid-body. Next, the female moved her anterior end around to face male #186, who began moving toward her while making jerky head movements. Male #186 assumed an outstretched position on top of the female and started making rapid full-body flexions. Male #186 next moved back toward male #245 while head bobbing and elevating the anterior portion of his body. Male #186 began laterally undulating the elevated portion of his body above male #245 and took a position stretched out on top of him. Next, male #186 paused his elevated undulations, moved toward the female, and began tongue flicking the cloacal regions of the copulating pair. During this time, the female moved around to face the same direction as male #245. Male #186 next moved back toward male #245 while head bobbing and resumed the elevated undulating behavior. The female slowly started moving away, dragging male #245 behind her with male #186 straightened out on top of him. Male #186 moved across and tongue flicked the cloacal regions again then moved to where the female had been previously, elevated his anterior end, and began undulating. After ceasing his undulations, male #186 remained still for a short period then moved away from the pair at 1308 h. Shortly thereafter, the female slowly moved off in the opposite direction dragging the conjoined male #245 behind her. We subsequently captured the snakes and measured snout–vent length (SVL) to the nearest millimeter with a flexible measuring tape and mass to the nearest gram with a Pesola spring scale. Sizes were as follows: male #186 (SVL = 68.1 cm, mass = 426 g), male #245 (SVL = 66.7 cm, mass = 315 g), female #246 (SVL = 61.9 cm, mass = 277 g).

When male #186 was initially encountered, he presumably was following a scent trail exuded by the female. On a previous occasion, one of us (DBS) observed the behavior of rapid tongue flicking and head probing by a different male *S. c. catenatus* after a female had recently been in the area. This behavior is undoubtedly a trail following behavior since male #186 led us to the female several meters away and moved in a seemingly direct path. Some behaviors exhibited by male #186 were not aggressive, but rather courtship behaviors directed toward the female. Specifically, the jerky head movements and full body flexions are involved in courtship and have been observed previously in *S. c. tergeminus* male-female pairs (Chiszar et al. 1976. Herpetologica 32:337–338). The behavior of vertically elevating the anterior portion of the body into an S-shape and laterally undulating has not been reported previously in *S. catenatus* and is probably specific to male-male aggressive interactions. The aggressive behavior of male #186 closely resembled that reported for *S. miliarius* (Carpenter 1979, *op. cit.*) in that both species elevate the anterior portion of the body at about a 45° angle, rarely perpendicular, and always in an S-shape, and laterally undulate with the objective to gain a superior position.

There is little opportunity for female choice in snakes because most mating is determined through male-male competition (Duvall et al. 1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 165–200. McGraw-Hill, Inc., New York). In species where males compete directly for females, males are predicted to be larger and the largest males should have the highest reproductive success (Shine 1994. Copeia 1994:326–346). In the genus *Sistrurus*, larger males are more likely to be associated with females during the mating season than smaller conspecifics (Bishop et al. 1996. Herpetologica 52:360–364; Phillips, unpubl. data). Even though male #186 was larger and theoretically should win in a bout, male #245 had already secured the mating. It appears that by tongue flicking the cloacal regions of the snakes, male #186 determined the pair was already copulating, and consequently moved away. In *S. c. catenatus*, males often remain with females for several days as part of an extended courtship/mate guarding association (D. Mauger, pers. comm.; Phillips, unpubl. data). It is during this period when a male is present with the female that the potential for male-male combat is highest as other males may be attracted to the area by female pheromones. Had male #245 not already been copulating, he may have responded aggressively toward the intruding male #186.

We thank the Illinois Department of Natural Resources, Illinois Wildlife Preservation Fund, U.S. Fish and Wildlife Service, and the U.S. Army of Corps of Engineers for funding, the IDNR and ACOE staff at Carlyle Lake for their support, and countless persons for field assistance. DBS also thanks L. Brown for insightful discussions.

Submitted by **DONALD B. SHEPARD, MICHAEL J. DRESLIK, CHRISTOPHER A. PHILLIPS,** and **BENJAMIN C. JELLEN**. Illinois Natural History Survey, Center for Biodiversity, 607 East Peabody Drive, Champaign, Illinois 61820, USA; e-mail (DBS): dbshepard3@hotmail.com.

TANTILLA MELANOCEPHALA (Black-headed Snake). **PREDATION.** The small colubrid *Tantilla melanocephala* is widely distributed from southern Guatemala to Peru, Bolivia, Brazil, and northern Argentina. It is considered mostly nocturnal in southeastern Brazil (Marques and Puorto 1998. Amphibia-Reptilia 19:311–318) and diurnal in the Amazonian region (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150). During a nocturnal driving avian census, we observed predation on *T. melanocephala* by the Burrowing Owl, *Athene cunicularia* (Aves: Strigidae). The observation occurred on 26 February 2002 at 1924

h on the border of an area of "campo cerrado" (shrubby grassland with scattered trees) with a *Eucalyptus* sp. plantation at Itirapina Ecological Station (IES); Brotas municipality, São Paulo State, southeastern Brazil; (22º12'38"S, 47º55'39"W, ca. 780 m elevation). The Burrowing Owl was spotted handling the snake on the border of an unpaved road. As we approached, the owl flew away. We examined the prey, an adult female *T. melanocephala*. Its body was divided in two parts, an anterior with 59 mm long and the posterior measuring 252 mm. The distance between them was ca. 400 mm. Contrary to other owls, *A. cunicularia* (145–185 g) is also diurnal, especially early in the morning and late in the afternoon, and occurs in open areas (Sick 1997. Ornitologia Brasileira. Ed. Nova Fronteira, Rio de Janeiro, Brazil; Voous 1989. Owls of the Northern Hemisphere. MIT Press, Cambridge, Massachusetts). Similarly, *T. melanocephala* occurs in open physiognomies, being the dominant species in the "campo cerrado" (R. J. Sawaya and M. Martins, unpubl. data).

Most South American reports indicate that burrowing owls feed mainly on insects and small vertebrates, with snakes largely absent from the diet (Schlatter et al. 1980. The Auk 97:616–619; Bellocq 1988. Physys, Secc. C 46[110]:17–22; Soares et al.1992. Biotemas 5[1]:85–89). However, the present observation adds to other predation events involving *Athene cunicularia* and snakes at IES (Martins et al. 2003. Herpetol. Rev. 34:147–148; Sawaya et al. 2003. Herpetol. Rev. 34:152–153). Moreover, 21 of 198 burrowing owl pellets from IES contained snake remains, totaling 10.6% of the sample (A. Bueno and J. C. Motta-Junior, unpubl. data). Also, Motta-Junior and Alho (2000. *In* Santos and Pires [eds.], Estação Ecologica de Jataí. Volume I. São Carlos: Rima Editora, 346 pp.) reported two snakes eaten by *A. cunicularia* in an area of cerrado vegetation in São Paulo State.

Thus, the burrowing owl appears to be an efficient predator of snakes in the open "cerrado" areas of Brazil. The voucher specimen of *T. melanocephala* cited above is deposited in the Museu de História Natural, Universidade Estadual de Campinas (ZUEC 02624). D. Zanchetta and the staff of Instituto Florestal allowed and facilitated our fieldwork at IES. We thank Ricardo J. Sawaya for suggestions on the manuscript, and Adriana Bueno for help with the English text. This publication is part of project "Natural History, Ecology, and Evolution of Brazilian Vertebrates" funded by FAPESP (00/12339-2). CNPq provided grant to MAMG (130935/00-0). This is publication number 11 of the project Ecology of the Cerrados of Itirapina.

TANTILLA NIGRICEPS (Plains Black-headed Snake). **MAXIMUM SIZE**. On 8 September 2001 we collected a female *Tantilla nigriceps* (354 mm SVL, 69 mm tail) in an open trench located at 35°07.519'N, 106°51.165'E; ca. 20.4 air km W Albuquerque (jct. Interstate 25 and Interstate 40), Bernalillo County, New Mexico, USA; 1805 m elevation. This exceeds the size record of a female (329 mm SVL, 61 mm tail) reported by Perry and Hauer (1996. Herpetol. Rev. 24:205–206). The specimen was catalogued in the University of New Mexico Museum of Southwest Biology (MSB 62817).

THAMNODYNASTES STRIGATUS (Corredeira). **DIET**. *Thamnodynastes strigatus* is a terrestrial snake that is found in low shrub and swampy areas. It has been reported to feed on amphibians, lizards and small rodents (Cei 1993. Mon. XIV Boll. Mus. Reg. Sci. Nat. Torino. 949 pp.; Achaval and Olmos 1997. Anfibios y Reptiles del Uruguai. Série Fauna N°1. 128 pp.; Marques et al. 2001, Serpentes da Mata Atlântica: Guia Ilustrado para a Serra do Mar. Holos Ed. 184 pp.).

On 16 February 2000 during a faunal rescue operation (Operação Graxaim) necessitated because of the flooding of Itá hydroelectric power plant reservoir, we collected a female specimen of *T. strigatus*. The snake was found on the east bank of the Uruguai River (27°22'42"S, 51°28'58"W), near Itá, Santa Catarina, Brazil (Centro de Estudos e Pesquisas Biológicas, Goiânia, Goiás - CEPB/IFS 043, SVL 557 mm). The snake had fed on a specimen of *Astyanax bimaculatus* (Actinopterygii: Characidae), SL/H = 59.32/17.6 mm. This represents the first record of a member of the genus *Thamnodynastes* preying on fishes.

We thank Rafael Braga do Amaral and Ricardo Brenner de Souza of Centro de Biologia Aquática (C.B.A.) of Universidade Católica de Goiás for helping with fish identification.

THAMNOPHIS ATRATUS (Coast Garter Snake). **ARBOREAL BEHAVIOR.** Although not typically considered arboreal, thamnophine snakes show arboreal tendencies on occasion (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. University of Oklahoma Press, Norman, 332 pp.). *Thamnophis proximus* may be the most arboreally inclined (Tinkle 1957. Ecology 38:69–77), and arboreal courtship behavior has been reported for *T. sirtalis* (Galbraith 2001. Can. Field-Nat. 115:347–348). Here I report arboreal behavior in a population of *T. atratus* in northern California.

On 12–13 June 2001, I observed > 20 adult *Thamnophis atratus* in shrubby growth (*Salix* sp. and *Populus fremontii*) bordering streams at Stebbins Cold Canyon Reserve, Solano Co., California, USA (38°29'N, 122°06'W). The snakes were in full sun or partial shade, usually looped loosely upon the branches, and appeared to be basking. Snakes were 20–200 cm above the water surface and usually solitary; however, there were instances when 2–4 snakes

were observed at different heights in the same shrub. On 13 June I observed a courtship event on the ground, but did not observe arboreal courtship behaviors or arboreal intraspecific interactions. All snakes appeared to be 30 cm TL or larger and several appeared heavy-bodied, although smaller snakes may have gone unnoticed. When disturbed, snakes dropped into the water and escaped into large cobble and boulders lining the stream. Observations on both days were made between 0900 h and 1400 h, temperatures varied between 24° and 30°C, and cloud cover was < 10%.

THAMNOPHIS BRACHYSTOMA (Short-headed Gartersnake). **DEFENSIVE BEHAVIOR.** Limited information exists regarding antipredator or defensive behavior in *Thamnophis brachystoma*. Tennant and Bartlett (2000. Snakes of North America: Eastern and Central Regions. Gulf Publishing, Houston, Texas. 588 pp.) report that this species is excitable, and not prone to bite. Hulse et al. (2001. Amphibians and Reptiles of Pennsylvania and the Northeast. Cornell University Press, Ithaca, New York. 419 pp.), reports that *T. brachystoma* does not bite, and that it will often thrash about violently, releasing feces and musk. Here I report a novel defensive behavior for *T. brachystoma*.

The observation was made on 6 May 2002, ca. 1100 h, just south of PA 36, adjacent to the Clarion River at Cook Forest State Park, Cooksburg, Pennsylvania, USA. An adult female *T. brachystoma* was found beneath a small flat rock. The snake immediately attempted to flee, making rapid undulations with its body. Upon being grasped, it thrashed about, musked, and voided the contents of its cloaca. After ca. 10 seconds of energetic writhing, the snake flattened its body dorsoventrally, opened its mouth, and began repeatedly striking at my left hand. Most of the strikes failed to make contact. Although it struck with open mouth, the snake never closed its mouth upon hitting my hand, and therefore did not bite. Additionally, its teeth never caught onto my skin, nor caused any abrasions. It continued to display this behavior for ca. 1 min, until placed on the ground and allowed to crawl beneath a rock. Flattening of the body caused the snake to appear larger than it was; whereas open-mouth strikes gave the snake a more threatening appearance. A second *T. brachystoma*, a mature male, was found in the same area. This individual did not display any behavior that was atypical for the species.

I thank W. Shane Snyder for accompanying me in the field. I also thank Arthur C. Hulse, James Ball, David Chiszar, and Hobart Smith for reviewing the manuscript.

Submitted by **BRIAN S. GRAY**, 1217 Clifton Drive, Erie, Pennsylvania 16505-5215, USA.

THAMNOPHIS RUFIPUNCTATUS (Narrow-headed Garter Snake). **REPRODUCTION.** Information on reproduction in *Thamnophis rufipunctatus* consists of data from Arizona (Rosen and Schwalbe. 1988. Status of the Mexican and Narrow-Headed Garter Snakes (*Thamnophis eques megalops* and *Thamnophis rufipunctatus rufipunctatus*) in Arizona. Arizona Game and Fish Department, Phoenix, Arizona. 50 pp. + appendices) and Chihuahua, Mexico (Rossman et al. 1996. The Garter Snakes. Evolution and Ecology, University of Oklahoma Press, Norman, 332 pp.). Here I report additional information on *T. rufipunctatus* reproduction from Chihuahua, Mexico.

Eight males (mean snout–vent length, SVL = 381 mm ± 58 SD, range: 290–479 mm) plus two immature males (SVL = 260 and 270 mm), and eight females (SVL = 470 mm ± 67 SD, range: 365–562 mm) plus two immature females from Chihuahua, Mexico were examined from the herpetology collection of the University of Arizona, Tucson (UAZ). Snakes were collected between 1958 and 1973. The left gonad was removed (except for UAZ 34335 which contained fetuses, and two immature females [UAZ 34160 and UAZ 34269]), and embedded in paraffin. Histological sections were cut at 5 µm, mounted on glass slides and stained with Harris' hematoxylin followed by eosin counterstain.

Three females from June were not undergoing yolk deposition (= secondary vitellogenesis, *sensu* Aldridge 1979. Herpetologica 35:256–261) (UAZ 34163, 562 mm SVL; UAZ 34271, 365 mm SVL; UAZ 35922, 450 mm SVL). One female from 17 June (UAZ 34335, 482 mm SVL) contained six fetuses. Two June females, UAZ 34160, 280 mm SVL and UAZ 34269, 286 mm SVL had small translucent follicles and were presumably sub-adults. Two females from July (UAZ 34276, 469 mm SVL; UAZ 36290, 400 mm SVL), one from September (UAZ 35236, 552 mm SVL) and one from December (UAZ 26461, 478 mm SVL) were not undergoing yolk deposition.

Six males from June were undergoing spermiogenesis (UAZ 34159, 332 mm SVL; UAZ 34266, 430 mm SVL; UAZ 34267, 360 mm SVL; UAZ 34272, 405 mm SVL; UAZ 34273, 479 mm SVL; UAZ 34274, 380 mm SVL). The testis from UAZ 34270, 270 mm SVL contained spermatogonia and primary and secondary spermatocytes. It may have started spermiogenesis later that year. Two males from July were undergoing spermiogenesis (UAZ 34275, 373 mm SVL; UAZ 34277, 290 mm SVL). The testis from (UAZ 34279, 260 mm SVL) contained spermatogonia and no spermatocytes. This snake was presumably a sub-adult.

Rosen and Schwalbe (1988, *op. cit.*) reported a mean clutch size of 11.3, range: 8–17 for three *T. rufipunctatus* from Arizona. Rossman et al. (1996, *op. cit.*) reported a clutch of 18 on 8 July for a female from Chihuahua, Mexico. The clutch of 6 reported herein is the smallest reported for *T. rufipunctatus*. The finding of non-reproductive females from June, July, September, and December suggests that only part of the female population produce young each year.

The presence of males undergoing spermiogenesis in June and July may suggest the testicular cycle of *T. rufipunctatus* is similar to that of *Thamnophis cyrtopsis* from Arizona (Goldberg 1998. Texas J. Sci. 50:229–234) in which spermiogenic males also occured during these months. My data have shown that in Chihuahua, Mexico male *T. rufipunctatus* reach maturity at 290 mm SVL

I thank G. Bradley (University of Arizona) for permission to examine specimens.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

THAMNOPHIS SAURITUS SAURITUS (Eastern Ribbon Snake). **DIET.** Ribbon snakes are semi-aquatic natricine snakes inhabiting low-lying wet areas. Amphibians appear to comprise the bulk of their diet, along with occasional invertebrates. Only one ambystomatid salamander (*Ambystoma maculatum*) has been documented as a prey item of *T. s. sauritus* (Carpenter 1952. Ecol. Monogr. 23:235–258; Rossman 1963. Bull. Florida St. Mus. Biol. Sci. 7:99–178). Here we report *A. talpoideum*, the mole salamander, as a prey item of the eastern ribbon snake.

On 22 July 2001 at 2212 h, a *Thamnophis s. sauritus* (38.3 cm SVL, 19.1 cm tail length, 15.0 g), was observed crossing U.S. Hwy 29 in Tuskegee National Forest, Macon County, Alabama, USA (32°26'31.4"N, 85°39'29.4"W). Upon capture the snake regurgitated one live adult and one partially digested adult *Ambystoma talpoideum* (3.8 g combined mass). The undigested salamander showed signs of tail movement upon regurgitation. The salamander was dead when examined ca. 16 h later. Both salamanders were deposited (AU 35565) in Auburn University's Paleo-Herp Museum and the snake was released at the point of capture.

We thank Craig Guyer, Bob Reed, and Robert Mount for comments.

Submitted by **MATTHEW P. GREENE** (e-mail: greenmp@auburn.edu) and **SCOTT M. BOBACK** (e-mail: bobacsm@auburn.edu), 331 Funchess Hall, Department of Biological Sciences, Auburn University, Alabama 36830, USA.

THAMNOPHIS VALIDUS (Mexican Pacific Lowlands Garter Snake). **REPRODUCTION.** Data on reproduction in *Thamnophis validus* is limited. Grismer (2002. Amphibians and Reptiles of Baja California, including its Pacific Islands, and the Islands in the Sea of Cortés. University of California Press, Berkeley. 399 pp.) found newborns during late summer and a female that produced ten young in August from Baja California del Sur. De Queiroz et al. (2001. Herpetol. Rev. 32:266) reported 13 offspring from a captive *T. validus* from BCS, Mexico. There are two accounts of *T. validus* litters from Sinaloa. Scott (1962. The Reptiles of Southern Sinaloa, Mexico. A taxonomic and Ecological Study. M. Sc. thesis, Humboldt State College, Arcata, California. 92 pp.) reported 20 young born on 13 July and Dixon and Webb (1965. Southwest. Nat. 10:140–141) reported 34 young born on 6 June. Conant (1969. Bull. Amer. Mus. Nat. Hist. 142:1–140) presented data on 7 litters born in captivity (mean = 17.4 ± 10.2 SD, range = 4–34). Rossman et al. (1996. The Garter Snakes: Evolution and Ecology, University of Oklahoma Press, Norman. 332 pp.) reported young born from 6 June to 1 August that varied from 165 to 223 mm in total length. Herein I provide additional information on the female reproductive cycle of *T. validus* from the Mexican mainland.

Reproductive data is presented from six females (mean snout–vent length, SVL = 608 mm ± 115 SD, range: 421–720 mm) from the herpetology collections of the Natural History Museum of Los Angeles County (LACM) and the University of Arizona, Tucson (UAZ). Snakes were collected 1963–1977. Information is also provided on a litter size deposited in UAZ from 1984. The left ovary was removed from LACM 103976, UAZ 37854,UAZ 37855 and embedded in paraffin. Histological sections were cut at 5 µm, mounted on glass slides and stained with Harris' hematoxylin followed by eosin counterstain.

Three females (LACM 103976, 709 mm SVL) collected 19 July from Sonora and (UAZ 37854, 421 mm SVL and UAZ 37855, 720 mm SVL) collected 2 August from Jalisco were undergoing yolk deposition (= secondary vitellogenesis, *sensu* Aldridge 1979. Herpetologica 35:256–261). One female (UAZ 37853, 535 mm SVL) collected 2 August from Jalisco contained eight enlarged ovarian follicles (11–15 mm length). Another female (LACM 103944, 600 mm SVL) from Sinaloa collected 16 August contained sixteen enlarged ovarian follicles (11–14 mm length). These females would have presumably finished yolk deposition the following year and ovulated. It appears yolk deposition in *T. validus* is completed over two reproductive seasons.

One female (LACM 103951, 663 mm SVL) collected 5 June from Sinaloa contained 22 developing young that were approximately one month from being born. Another female (not in UAZ) collected 21 September in Sonora produced 29 neonates, (UAZ 45436–45464, mean SVL = 157 mm ± 12 SD, range: 115–171 mm). Four were stillborn on 21 September, while 25 were born live on 26 October. Mean SVL of the full-term snakes (160 mm ± 7 SD, range: 143–171, N = 25) was significantly larger than that of the stillborn snakes (136 mm ± 15 SD, range:115–150, N = 4) Mann-Whitney U-statistic = 2.00, P = 0.003.

I thank D. Kizirian (Natural History Museum of Los Angeles County) and G. Bradley (University of Arizona) for permission to examine specimens. K. Beaman (Natural History Museum of Los Angeles County) provided comments on the manuscript.

TALLGRASS PRAIRIE AMPHIBIAN AND REPTILE ASSEMBLAGE. FIRE MORTALITY. On 30 October 1999, from ca. 1000 h to 1300 h, I surveyed ca. 33 ha of a 65-ha virgin tallgrass prairie (Penn-Sylvania Prairie) in Dade County, Missouri, USA, for evidence of vertebrate mortality resulting from a prescribed burn conducted on 28 October 1999 at ca. 1600 h. The 30th of October was a cool (< 10°C) and overcast day, with a light drizzle of rain. I walked the prairie in a zig-zag pattern traveling back and forth the length of the burned area. I observed a total of 72 individual herps, consisting of 8 species of reptiles and 1 species of amphibian on the burned portion of the prairie. The species followed by the numbers observed alive and dead, respectively, included: *Bufo americanus* 1, 0; *Terrepene carolina* 22, 20; *T. ornata* 3, 4; *Ophisaurus attenuatus* 0, 2; *Coluber constrictor* 0, 3; *Elaphe obsoleta* 1, 1; *Lampropeltis calligaster* 0, 12; *Opheodrys aestivus* 1, 0; *Thamnophis sirtalis* 1, 1; Total 29, 43.

Several *T. carolina* and *T. ornata* (both dead and alive) were found partially hidden in shallow burrows or forms. Over 50% of *T. carolina* were found in several formerly brushy draws, now denuded of vegetation from the burn. Four days of warm weather (> 18°C daytime temps) preceded the burn date and temperatures on 28 October were > 20°C, which probably stimulated reptile activity and resulted in higher reptile mortality than during other fall burns. These observations emphasize the need to implement prescribed burns during cool, overcast periods or after most reptiles are dormant as to avoid high reptile mortality.

GEOGRAPHIC DISTRIBUTION

Herpetological Review publishes brief notices of new geographic distribution records in order to make them available to the herpetological community in published form. Geographic distribution records are important to biologists in that they allow for a more precise determination of a species' range, and thereby permit a more significant interpretation of its biology.

These geographic distribution records will be accepted in a **standard format** only, and all authors *must* adhere to that format, as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother 2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. SSAR Herpetol. Circ. 29:1–82; for Mexico as it appears in Liner 1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*. Herpetol. Circ. 23:1–113), LOCALITY (use metric for distances and give precise locality data), DATE (day-month-year), COLLECTOR, VERIFIED BY (*cannot* be verified by an author—curator at an institutional collection is preferred), PLACE OF DEPOSITION (where applicable, use standardized collection designations as they appear in Leviton et al. 1985, *Standard Symbolic Codes for Institutional Resource Collections in Herpetology and Ichthyology*, Copeia 1985[3]:802–832) and CATALOG NUMBER (required), COMMENTS (brief), CITATIONS (brief), SUBMITTED BY (give name and address in full—spell out state names—no abbreviations).

Some further comments. This geographic distribution section does not publish "observation" records. Records submitted should be based on preserved specimens which have been placed in a university or museum collection (private collection depository records are discouraged; institutional collection records will receive precedence in case of conflict). A good quality color slide or photograph may substitute for a preserved specimen *only* when the live specimen could not be collected for the following reasons: it was a protected species, it was found in a protected area, or the logistics of preservation were prohibitive (such as large turtles or crocodilians). Color slides and photographs *must* be deposited in a university or museum collection along with complete locality data, and the color slide catalog number(s) must be included in the same manner as a preserved record. Before you submit a manuscript to us, check Censky (1988, *Index to Geographic Distribution Records in Herpetological Review: 1967–1986*; available from the SSAR Publications Secretary) to make sure you are not duplicating a previously published record. The responsibility for checking literature for previously documented range extensions lies with authors. Do not submit range extensions unless a thorough literature review has been completed.

Please submit any geographic distribution records in the **standard format only** to one of the Section Co-editors: **Alan M. Richmond** (USA & Canadian records only); **Jerry D. Johnson** (Mexico and Central America, including the Caribbean islands); **Hidetoshi Ota** (all Old World records); or **Gustavo J. Scrocchi** (South American records). Short manuscripts are discouraged, and are only acceptable when data cannot be presented adequately in the standard format. **Electronic submission of manuscripts is required** (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments. Refer to inside front cover for e-mail addresses of section editors.

Recommended citation for new distribution records appearing in this section is: Marques, O. A. V., and G. Puorto. 1996. Geographic Distribution. *Chironius laevicollis*. Herpetol. Rev. 27:212.

CAUDATA

AMBYSTOMA OPACUM (Marbled Salamander). USA: VIRGINIA: Scott Co: Rikemo Lodge, ca. 1 km SW of Dungannon. 8 May 1999. Christopher S. Hobson, Steven M. Roble, Anne C. Chazal. Verified by Richard Hoffmann. Virginia Museum of Natural History (VMNH) 10337. Sub-adult found in a small pit (ca. 0.25 m deep) covered by a piece of plywood at Rikemo Lodge, situated on a slope just above the floodplain of the Clinch River. First record for Scott Co., and first published record for southwestern Virginia (Mitchell and Reay 1999. Atlas of Amphibians and Reptiles in Virginia. Spec. Publ. No. 1, Virginia Department of Game and Inland Fisheries, Richmond, Virginia. 122 pp.; Tobey 1985. Virginia's Amphibians and Reptiles: A Distributional Survey, Virginia Herpetological Survey, Purcellville, Virginia, 113 pp.). The nearest published records within the Ridge and Valley physiographic province are from Knox County, Tennessee (ca. 160 km SW), and Montgomery County, Virginia (ca. 180 km NE) (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, Center for Field Biology, Austin Peay State University, 94 pp.; Tobey 1985, *op. cit.*). This record partially fills a hiatus in the known range for this species that includes much of the southern Appalachians; northeastern Kentucky and Tennessee, western North Carolina, and southwestern Virginia (Conant and Collins 1991. Reptiles and Amphibians of Eastern/Central North America. Houghton Mifflin Co., Boston, Massachusetts, 450 pp.).

Submitted by **CHRISTOPHER S. HOBSON** (e-mail cshobson@dcr.state.va.us) and **STEVEN M. ROBLE** (e-mail: sroble@dcr.state.va.us), Virginia Department of Conservation and Recreation, Division of Natural Heritage, 217 Governor Street, Richmond, Virginia 23219, USA.

AMBYSTOMA MACRODACTYLUM (Long-Toed Salamander). USA: CALIFORNIA: Tehama Co: Lassen National Forest, Cascade Range, Carter Meadow (40°1324.78"N, 121°24'43.76"W) 1860 m elev. 5 August 2002. Chris R. Feldman and Daniel G. Mulcahy. CAS 225059–60. Verified by Jens Vindum. New county record (Vindum and Koo 2002, Amphibians and Reptiles of the Lassen National Forest: Results of 02-CS011050650-029, the 2002 California Academy of Sciences Survey). The nearest known localities are: 18.5 km S (Coon Hollow, Butte Colorado; MVZ 60909), 12.6 km E (6.4 km SW of Chester, Plumas Co.; MVZ 50204), and 18.3 km N (Bunchgrass Creek, Plumas Co.; CAS 225057). We found the two adult salamanders inside decaying logs in a closed canopy portion of the meadow. In northeastern California, *A. macrodactylum* occurs in mid-elevation meadows, ponds, and lakes. Such habitat is common in the northern Sierra Nevada and southern Cascade Mountains, and *A. macrodactylum* is likely contiguous throughout this region.

We thank Michelle Koo, Jens Vindum, Melanie McFarland, and Ken Roby for supervision during field surveys, which were funded by Challenge Cost-Share Agreement #02-CS-11050650–029, Forest Service Region 5, Lassen National Forest.

Submitted by **CHRIS R. FELDMAN** (e-mail: elgaria@biology.usu.edu) and **DANIEL G. MULCAHY** (e-mail: dmulcahy@biology.usu.edu), Department Biology, Utah State University, Logan, Utah 84322-5305, USA.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). USA: TENNESSEE: Sullivan Co: South Holston Weir Dam, 50 m E of intersection of Holston View Dam Road and TVA Road South (36.5218N, 82.1064W). 7 March 2002. Kevin Hamed and Phil Gentry. Verified by A. Floyd Scott, Austin Peay State University Museum of Zoology, APSU 3344. First record from Sullivan County and second record from upper East Tennessee (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ.

Herpetological Review

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

Society for the Study of Amphibians and Reptiles

www.ukans.edu/~ssar

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

Annual Dues and Subscriptions: Annual membership dues for the year 2003 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ukans.edu/~ssar/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with Visa or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Peabody Museum of Natural History, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Fax: (203) 432-5176; e-mail: theodora.pinou@yale.edu

Future Annual Meetings

2003 — Hotel Tropical, Manaus, Brazil, 26 June–1 July (with ASIH, HL)
2004 — University of Oklahoma, Norman, Oklahoma (with ASIH, HL)
2005 — University of South Florida, Tampa, Florida (with ASIH, HL)

SSAR BUSINESS

SSAR Announces the Dean E. Metter Memorial Award

Dean E. (Doc) Metter (1932–2001) was a long-time member of the biology faculty at the University of Missouri-Columbia, where he taught zoology, comparative anatomy, evolution, and herpetology. A believer in putting knowledge to the test in the field, Doc provided frequent opportunities for students to engage in fieldwork. In addition, he frequently assisted his graduate students as they ventured out to collect data.

Doc was a co-founder of the Bobby Witcher Society, the legacy of which is a scholarship fund. For many years, the interest earned served to reward outstanding herpetology students who intended to continue their education and seek a career in vertebrate biology. That fund now serves a similar purpose by honoring Doc's memory while helping to fund the SSAR-administered Dean E. Metter Memorial Award.

The purpose of the Award is: (1) to honor the memory of Dean E. Metter; (2) to encourage students to pursue field research in herpetology; and (3) to facilitate field research in herpetology by providing funds for relevant expenses. Grants made from the award will be no less than US $300 and no more than US $1,000. Efforts will be made to fund as many eligible proposals as possible. Applicants must be currently enrolled as an undergraduate or graduate student in an accredited college or university and be conducting field-based research in herpetology. This research may occur anywhere in the world, but priority will be given to research conducted in the state of Missouri. Expenses eligible for funding include: (1) travel expenses (e.g., mileage, airfare) associated with the field research project; and (2) equipment for field-based research (e.g., materials for drift fences, traps, etc.). Funds may not be used for salaries or any other personnel expenses, travel to

About Our Cover: *Echis carinatus*

The genus *Echis* Merrem, 1820—the saw-scaled vipers—includes, depending on authority, between 8 and 12 xeric-region species, widespread from Africa to southern Asia (Cherlin 1981. Proc. Zool. Inst. Acad. Sci. U.S.S.R. 1981:92–95; 1990. Proc. Zool. Inst. Leningrad 207:193–223; Cherlin and Borkin 1990. Proc. Zool. Inst. Leningrad 207:175–193 [all in Russian, with English abstracts]; David and Ineich 1999. Les serpents venimeux du monde: systématique et répartition. Dumerilia 3:3–499; McDiarmid et al. 1999. Snake Species of the World. A Taxonomic and Geographic Reference. Volume 1. The Herpetologists' League, Washington, D.C. xi + 511 pp.). These small snakes arguably take the greatest toll of human lives among all venomous snakes because of their extremely toxic venom, and are thus of great medical importance. In India, a densely populated country with a large rural population, annual snake-bite mortality was estimated to be as high as 20,000–40,000 a year (Swaroop and Grab 1954. Bull. World Health Org. 10:35–76), with a high proportion attributed to the saw-scaled viper.

When threatened, these snakes produce a characteristic sizzling sound, likened to "water sprayed on hot coals" (Leviton et al. 1992. Handbook to Middle East Amphibians and Reptiles. SSAR Contrib. Herpetol. 8, Oxford, Ohio. vi + 252 pp; 33 pl.) that is produced by rubbing the parallel body coils against each other, causing the obliquely aligned keel of the third through ninth dorsal scale rows to come in contact (see Kimmich and Blaney 1973. HISS News-J. 1(3):85). The sound thus produced is a stridulation, replacing hissing in many other members of the family, and is presumably an adaptation for living in xeric regions (hissing or expiration results in some moisture loss).

The eastern representative of the genus is the widespread *Echis carinatus*, known from Pakistan, peninsular India, and Sri Lanka, its distribution extending to the Middle East. Several subspecies names have been applied, under the Biological Species/Typological Species Concepts, to the Subcontinent's populations (see for instance, Auffenberg and Rehman 1991. Bull. Florida Mus. Nat. Hist., Biol. Sci. 35[5]:263–314), including the nominate *carinatus* (Schneider, 1801) from the Indian Peninsula, *astolae* Mertens, 1970 from Astola Island, off the Balochistan coast of Pakistan, *multisquamatus* Cherlin, 1981 from the mountains of northern Pakistan, Afghanistan, Iran, Central Asia and the Middle East, *sinhaleyus* Deraniyagala, 1951 from northern and eastern Sri Lanka, and *sochureki* Stemmler, 1969 from Afghanistan, the lowlands of Pakistan, northern India, and seemingly also Bangladesh. Phylogenetic relationships of these populations remain unstudied.

The cover photograph depicts an adult *Echis carinatus* on the sand dunes of Thar Desert, Rajasthan State, western India, at sunrise. The population is allocated to the subspecies *sochureki*, named for the Austrian herpetologist, Erich Sochurek (1923–1987). On dunes, the typical mode of locomotion is sidewinding, and such tracks are commonly seen over undisturbed sandy stretches of the Thar. This easily-roused species is nocturnal, feeding on small mammals such as rodents, as well as birds and perhaps also lizards, and up to 20–25 live young are produced at a time (Whitaker 1978. Common Indian Snakes: A Field Guide. Macmillan India Limited, New Delhi. xiv + 154 pp; Khan 2002. The Snakes of Pakistan. Edition Chimaira, Frankfurt am Main. 265 pp).

PHOTO BY AARON BAUER

Indraneil Das, who photographed the snake on 27 October 2002, used a handheld Nikon F5, with a 24–50 mm 1:3.3–4.5 D AF Nikkor lens to record the image on Fujichrome Velvia (50 ASA) film. Illumination was provided by a F-28 Speedlight flash unit, with an additional SB-27 Speedlight flash unit set on a tripod as a slave.

Das is Associate Professor with the Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak, and has worked on the herpetofauna of tropical Asia for about 20 years. He received his doctorate from the University of Oxford, and was a Fulbright Fellow at the Museum of Comparative Zoology, Harvard University, and Scientific Officer at the Centre for Herpetology, Madras Crocodile Bank Trust. Among his publications are works on ethnobiology, biogeography, systematics, nomenclature, and field guides to Asian amphibians and reptiles, including a new guide to Indian reptiles, **"A Photographic Guide to the Snakes and other Reptiles of India"** (New Holland Publishers [UK] Ltd, 2002). He is also the Editor of the herpetological journal *Hamadryad*, now in its 27th volume.

meetings, equipment or supplies for laboratory-based research (even if applicable to the project), or overhead or indirect costs.

Application details and selection criteria are available on the SSAR webpage (www.ssarherps.org). *Please note that the application deadline is 15 July 2003.*

2002 Annual Meeting: Kansas City, Missouri

The 45th annual meeting of SSAR took place from 3 to 8 July 2002 in Kansas City, Missouri. The Society met jointly with the American Elasmobranch Society (AES), the American Society of Ichthyologists and Herpetologists (ASIH), and The Herpetologists' League (HL). This event was hosted by Ed Wiley and the University of Kansas at the Westin Crown Center Hotel. More than 1100 registrants packed the Westin's facilities during the Independence Day weekend. Approximately 725 oral and poster presentations on herpetological and ichthyological research activities provided the focus for scientific discussion over the 5 days of the event.

Social Programs

A series of social events provided lively diversion from the daily scientific presentations. Wednesday evening saw the presentation of the SSAR President's Travelogue. Slide presentations featured stories and images of the herpetofauna of Africa. SSAR President David Green's presentation entitled "Travels in Kenya: Pondscape with Frog," highlighted anurans from a variety of ecological settings. David was quick to point out the occasional squamate as well. Wolfgang Böhme (Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn, Germany) kept an appreciative crowd entertained with his presentation entitled "Between Rainforest and Desert: Herpetofaunal Travels in West and Central Africa," which featured crocodiles living in extreme environments. Evening activities were augmented by a cash-bar social at the *Brasserie Lounge*, in the lobby area of the Westin Crown Center Hotel. This venue served as a focal point for many social gatherings. On the morning of 4 July, the Opening Plenary Session began with a series of introductory comments by Bob Cashner, who gave way to presentations by Brooks Burr (ASIH), and Merry Camhi (AES). George Zug gave the Distinguished Herpetologist Lecture. In honor of The Herpetologists' League 50th Anniversary Presentation, Whit Gibbons had the audience wondering why he did not take up a career as a stand-up comic. Following the opening session, hordes of attendees gathered on the roof of the hotel lobby to pose, in the mid-summer heat and humidity, for the obligatory meeting photograph. Thursday evening, 4 July, provided meeting participants with the opportunity to view the latest versions of the David Dennis and Eric Juterbock slide presentations of regionally distinct herpetofauna, coupled with a historically oriented slide show by Dennis, Juterbock, and Kraig Adler. A patriotic explosion of herpetological sights and sounds were a treat for the crowd that packed the Liberty Room of the conference facilities.

SSAR sponsored the Eighth Annual Student Awards Frameable Art Silent Auction to raise funds to offset student travel expenses. Glen Lubcke and John Campbell organized this successful activity that saw active bidding on numerous items of herpetological art, literature, and culture on Thursday through Saturday of the meeting. Kirsten Nicholson organized the SSAR Graduate Student Reprint and Book Grab to provide young herpetologists with the opportunity to gain access to scientific literature. Thanks are extended to the many contributors to these special events.

On Friday (5 July), the annual meeting auction was again cosponsored by SSAR and The Herpetologists' League with pro-

During the Plenary Session, SSAR honored the two Society founders Kraig Adler and David Dennis (left and right, above), with plaques of appreciation presented by SSAR President David Green. Adler and Dennis, who founded The Ohio Herpetological Society in 1958, together with a small group of mostly teenaged amateur herpetologists developed the OHS into an organization with national and even international activities. The society changed its name to SSAR in 1967. Jim Murphy was instrumental in the production of the plaques and in the conspiracy of secrecy leading up to their presentation.

Whit Gibbons (left) confers with Herpetologists' League President Ken Dodd following Whit's humorous retrospective of meetings and personalities over the first 50 years' of HL history.

ceeds from the event being split between the two societies. David Morafka and John Moriarty conducted the auction while a variety of students helped with displaying items for members of the audience. Key SSAR Board members generously passed out drink tickets, adding to active bidding on a variety of herpetological items, thus carrying activities well into the evening and providing significant financial support for this year's meeting. Some truly outstanding items saw exceptional bidding, but all auction material was well received and greatly appreciated. The evening of Saturday, 6 July, saw meeting participants congregated in the confines of the historic Union Station Sprint Festival Plaza for the Annual Barbecue. Attendants dined on famous Kansas City barbeque and a variety of side dishes. Many herpetologists and ichthyologists found the locally produced ales and lagers to be quite pleasing, and kept the taps flowing into the evening. Live music filled the spacious venue while participants ate, drank, and engaged in stimulating conversation.

Business Meeting and Board Meeting Summary

The Annual SSAR Business Meeting was called to order by Society President David Green at 1605 h on 6 July 2002 at the Westin Crown Center Hotel in Kansas City, MO. In addition to board members, journal editors, and committee coordinators, the business meeting was sparsely attended by approximately two dozen Society members.

President Green summarized reports made by the SSAR Board of Directors by outlining key points from that meeting earlier in the week: President Green announced several new appointments made during 2002. New appointments included Maureen Kearney (Elector for 2002 elections), Julian Lee (Chair of Nominations Committee), and Al Savitzky (SSAR representative to AIBS). Additionally, President Green appointed several individuals to serve on several committees for the Society: Brian Crother (Chair), Beth Dawson, Malcolm McCallum, and Laurie Vitt (representatives to the joint SSAR/HL Task Force on electronic publishing), and Breck Bartholomew, Lee Fitzgerald (Chair), John Matter, and George Pisani (as an *ad hoc* Task Force to make recommendations on SSAR's new website). All outgoing editors and officers were thanked for their thoughtful and diligent service to the Society.

Outgoing Society Treasurer Robert Aldridge, in conjunction with his successor, Theodora Pinou, reported that SSAR remains financially viable with total assets of $481,038 ($241,432 being represented by restricted funds). Bob reported that Society budget items for FY 2002 came to $252,296, while SSAR realized income totaling $303,351 from the preceding year. Looking to the future, Dora Pinou stated that various Society entities could be viewed as small businesses and need to set individual goals for financial stability. Aldridge and new Publications Secretary Breck Bartholomew reported that the sale of SSAR publications totaled $110,807. Of this amount, significant revenues were realized from the sale of Bill Duellman's revised edition of "Hylid Frogs of Middle America" and David Dennis' original watercolors from the 1970 edition of that volume. Both Aldridge and Bartholomew noted that the Society sees significant expenses in housing and transporting the current volume of published material. President Green requested that Bartholomew identify ways to decrease the current inventory and recommend adjustments to future publication runs. Bob Aldridge reported that SSAR membership remained relatively stable, at 2255 for FY 2002. Domestic regular and student members represent the largest of the various Society membership categories, while declines in foreign memberships are viewed as the most significant losses. Discussions by the Board considered the formation of a working group to collaborate with ASIH on how to deal with endowment funds. President Green appointed Dora Pinou, Gabriela Parra, and Robert Aldridge to make recommendations with respect to managing funds for the Bailey, Metter, Gordon, and Minton endowments.

Journal of Herpetology Editor, Brian K. Sullivan (*in absentia*), submitted a report outlining significant happenings with the *JH* for 2001–02. A number of personnel changes were reported. David Sever resigned as Associate Editor, while Maureen Donnelly, Mike Harvey, and Howard Whiteman accepted positions to the Editorial Board. Brian reported that submissions to the *Journal* continue to grow, being 284 in 2001, up from 262 manuscripts during 2000. Of these submissions, 81 were accepted, representing a 34% acceptance rate. Submissions as of June 2001 were running 20% higher than a comparable date in recent years, and could reach record levels. Sullivan reported that publication lag times of 9–12 months could be expected for accepted manuscripts, noting that decreasing that time could incur significant costs for the Society. Sullivan endorsed several recommendations made by the Publications Task Force that had been chaired by William Cooper: 1) Changing the *Journal of Herpetology* to a glossy paper stock (a change that Sullivan reports has been implemented and well received). 2) Increasing the font size of the *Journal* from its current 9 pt (for Article text) and 8 pt (for citations and Shorter Communications) to 10/9 pt (for text and citations in Articles) and 9 pt (for Short Communications). Sullivan estimated that increasing font

Meeting attendees crowded into the Union Station Sprint Festival Plaza for the annual barbecue. From left to right, Wolfgang Böhme, Karl-Heinz Jungfer, and Edgar Lehr offered diplomatic assessments of American beer.

size represents a potential increase in page numbers that would result in added publication costs. 3) Implementing the addition of abstracts to Shorter Communications (a change that is anticipated for 2003). The Board approved the idea of adding abstracts to Shorter Communications. However, it felt more information was needed before deciding on the issue of increased font size for the *Journal of Herpetology*. Sullivan reported that budgetary costs of *JH* for FY 2001 were $87,996—$6,486 over that approved with significant increases in mailing costs being responsible for the overrun. Brian's budget request of $101,000 for FY 2003 is designed to increase pages published in the *Journal of Herpetology* and decrease the lag in publication time.

Herpetological Review Editor, Robert Hansen, reported numerous personnel changes in the *Herp Review* editorial staff. Joseph Collins stepped down as Section Editor (Geographic Distribution) following 12 years of distinguished service in that post. Alan Richmond has been appointed to fill the position vacated by Collins. Outgoing Associate Editors for 2002 include Adam Summers and Sharyn Marks. Robert Espinoza was appointed to replace Summers, and other candidates are being considered for the remaining position. Other personnel changes at *Herp Review* include the departures of Brian Hauge (Section Editor, Natural History Notes), Winston Card (Section Editor, Herpetological Husbandry, replaced by Ruston Hartdegen), Jennifer Pramuk (Copy Editor, replaced by Hugo Alamillo), and Brian Butterfield (Section Editor, Natural History Notes). Additional new appointments include Marc Hayes (Section Editor, Natural History Notes—lizards, crocodilians) and Jim Harding (Section Editor, Natural History Notes—turtles). Jim Murphy serves as Section Editor for the "Zoo View" feature that made its debut in 2002. Hansen reported that Volume 32 of *Herp Review* consisted of 292 pages (an increase of 20 pages from the preceding volume) and projected that Volume 33 would run 320 pages. Hansen noted that *Herp Review* seems to be able to maintain its current, expanded production size (80 pages per issue) and hopes to decrease publication lag time. Hansen reported that production of *Herp Review* has evolved to an increasingly digital process, noting that Volume 32 was sent to the printer on CD, and that this has allowed for increased page numbers at a constant cost to the Society.

Robert Powell, Editor of the *Catalogue of American Amphibians and Reptiles* (*CAAR*), reported on the status of this publication effort. Bob noted that the 2001 contributions to *CAAR* consisted of 20 accounts (Nos. 721–740; 1 caecilian, 1 salamander, 1 frog, 2 turtle, 4 lizard, and 11 snake accounts) for a total of 108 printed pages. Color plates were included in 17 of the accounts. Bob anticipated the completion of 20 accounts for 2002 (with 19 of these having color plates) and has plans for another 20 accounts for 2003. Powell is concerned that there are insufficient numbers of individuals submitting species accounts (particularly on Central and South American taxa) to maintain the annual production rate of 20 *CAAR* accounts. Bob's requested budget ($12,000) would allow for much-needed technology upgrades in addition to the usual production and mailing charges. Powell expressed a desire to convert *CAAR* accounts from hardcopy material to CD ROM format to keep production costs down.

Kraig Adler (Editor) reported on the publication activities of *Contributions to Herpetology*. Recent publications in this series include the two-volume, revised edition of "Hylid Frogs of Middle

The annual banquet made for a lively ending to the meetings. From left to right: José Rosado, Greg Watkins-Colwell, Chuck Crumley, Al Richmond, Eric Hilton, and Nate Kley salute the high quality of scientific presentations they witnessed throughout the course of the meetings.

America," by William E. Duellman (with new artistic renderings by David Dennis; released at the annual meeting in Indianapolis, July 2001) and "Amphibians of Honduras," by James McCranie and Larry David Wilson (February 2002). Adler reported on publication projects due in 2003. These projects include the long-anticipated "Field Guide to Amphibians and Reptiles of the West Indies," by S. Blair Hedges (the first color-illustrated guide to the herpetofauna of the entire West Indies) and "Biology of the Reptilia, Volume 20 (Morphology)," edited by Carl Gans and Abbot Gaunt. Ernie Liner's comprehensive index to "Biology of the Reptilia," is anticipated shortly after the publication of Volume 20, and would represent Volume 21 of this long-running series. "Lizards of Southern Africa," to be edited by William Branch and Aaron Bauer, is expected in the foreseeable future and will have contributions from authorities on this specific geographic location.

Editor of the *Facsimile Reprints in Herpetology*, Aaron Bauer, reported on the successful completion of a project through this Society series as well as anticipated contributions expected in the future. The reprint edition of "Anatomy of the Salamander," by Eric Francis, including a new introduction by James Hanken and editorial ministrations by Kraig Adler, was published in March 2002. Originally issued in 1919, "Herpetology of Cuba," by Thomas Barbour and C.T. Ramsden, will receive an updated taxonomic treatment (including cross listing of nomenclature used in the original with their currently recognized names), and is expected by May of 2003. Rodolfo Ruibal is providing a new introduction to this reprinted monograph. Herpetological bibliophiles will also relish the reprinting of 65 papers from the late 1880s through 1917 by Italian Mario Giacinto Peracca. Due to be published late in 2003, "The Herpetological Contributions of Mario Giancinto Peracca," will be edited by Franco Andreone and Elena Gavetti and have an English translation of the introduction. Bauer outlined future projects that include "Les Tortues de l'Indochine," by René Bourret and "The Herpetological Contributions of John Edward Gray." The work on Indochinese turtles will include a biography of Bourret and current taxonomy and systematics for turtles of this region. The other project will combine many of the shorter herpetological works by Gray that have not been included in earlier SSAR reprints by this classical author.

Herpetological Circulars Editor, John Moriarty, reported that

completion of *HC No. 31*, "Conservation Guide to the Eastern Diamondback Rattlesnake," by Walt Timmerman and Marty Martin, has been delayed. The Guide is expected to be completed and available in 2003. "Herpetological Collecting and Collections Management, revised edition," (*HC No. 32*) by John Simmons was published in September 2002, and represents a fully revised and expanded version of *Herp Circular No. 16*.

Stephen Corn, departing Editor of *Herpetological Conservation* reported that Volume 2 in this series, "Ecotoxicology of Amphibians and Reptiles," has been terminated. Corn noted that there was insufficient material in the submitted manuscripts to warrant publication of a book, and that authors of those chapters had been referred to *Applied Herpetology* as a viable outlet for this material. Volume 3, "Conservation and Status of Reptiles in Canada," edited by Carolyn Seburn and Christine Bishop, with additional editorial support by Patrick Gregory, has been reassigned as Volume 2 in the *Herp Conservation* series. In addition to publication support by SSAR, financial backing by The Canadian Amphibian and Reptile Conservation Network ensures the completion of this work during 2003. Members of the SSAR Board discussed the future of this series, which is in need of an editor and seems to (in Corn's opinion) lack sufficient manuscript submissions to exist as a regular publication. The Board felt that *Herpetological Conservation* is a worthy series; an ad hoc committee of Board members was formed to suggest names of potential editors to the President.

A proposal was made to the Board to change the election schedule from annual elections to biennial elections. Discussion followed and another recommendation was to increase the size of the Board from 6 members to 8 members. The membership at the Business meeting voted in favor of these recommendations. Increasing the size of the Board and changing the length of Term of Office requires a change in the SSAR bylaws and will be voted on in the 2003 election.

The Board received reports from Committee Chairs for Grants-in-Herpetology (Erik Wild), Kennedy Student Award (Robert Gatten), and Seibert Awards (Marion Preest). Details have been published in *HR* (33:161–162 and 33:242).

Related to issues of student support and funding, Robert Powell announced a new award that will be implemented by SSAR. The Dean E. Metter Memorial Award is designed to make funds available for student projects related to field research in herpetology. Funds for this award were made available by the Bobby Witcher Society and are in recognition of the late Dean E. Metter, a long-time member of the faculty at the University of Missouri at Columbia and SSAR member. The Metter Awards will generally be in the amount of $300 to $1000.

Mike Plummer, Chair of the Conservation Committee, reported that the committee continues to build on a strong web-based education effort. To date, 35 of 50 U.S. states have been linked to material on the SSAR Conservation Website. Members of the committee include Kurt Buhlmann, Ken Dodd, Mike Dorcas, Lee Fitzgerald, John Jensen, Andy Price, Steve Sheffield, and Mike Sredl. Other efforts for the year consisted of writing and sending a position letter to the U.S. Fish and Wildlife Service (USFWS) endorsing the listing of *Clemmys guttata*, all North American *Apalone* spp., *Crotalus adamanteus*, *Crotalus horridus*, and *Lampropeltis zonata* to Appendix II of CITES.

Richard Wassersug presented a proposal to the Board to set up a service in which SSAR members would do preliminary editing of manuscripts written in English by our colleagues who do not have English as a first language. A list of SSAR members willing to be involved in this project will be available on the SSAR website (http://www.ssarherps.org/pages/presub.html). Persons who have manuscripts ready for submission (to any journal) can peruse this list of SSAR members and select an appropriate person with whom to correspond. Members of the SSAR community may offer to read and edit up to three English language manuscripts per year within their specific area of herpetological expertise. This service would be provided free to herpetologists whose first language is not English, but who are striving to publish their findings in peer-reviewed English language journals. The Board unanimously approved this project.

Henry Mushinsky presented information on plans for future meetings. The SSAR Board approved and accepted meeting invitations for the next several years. These meetings will be joint events with the American Society of Ichthyologists and Herpetologists (ASIH) and The Herpetologists' League (HL). In 1999, SSAR entered into a Joint Meeting Planning Committee relationship with members of ASIH, HL, and the American Elasmobranch Society (AES). Mushinsky provided details for future dates: 2003, Manaus, Brazil (June); 2004, Norman, Oklahoma (27 May–2 June); 2005, Tampa, Florida; 2006, New Orleans, Louisiana; and 2007, Ithaca, New York. The 2003 meeting will take place at the Hotel Tropical, which is situated along the banks of the Rio Negro in Manaus. Local committee member Richard Vogt provided videotaped scenes of celebrations in Manaus and details about the meeting location and early registration and travel information. Vogt stated that the Hotel Tropical is a top-rated resort with many amenities and comfortable accommodations. He personally guaranteed that meeting delegates would have a memorable experience.

Dawn Wilson, Chair of the SSAR Travel Awards Committee, noted that money from the silent auction this year will be used to provide travel awards for the 2003 meeting in Manaus. 2003 travel awards will be $400 instead of the usual $200 because of the distant locale of the meeting.

Ron Heyer requested that SSAR donate $5000 toward the next World Congress of Herpetology. After considerable discussion, the Board indicated its willingness in principle to support WCH; however, it was felt that more information on the venue and timing of the next congress would be necessary before funds could be committed.

Logistical concerns related to growth of the Annual Meeting have led to increased involvement between the societies with herpetological interests. A number of policy changes have been considered by the SSAR Board in association with mandates set down by the Meeting Planning Committee (MPLN). Henry Mushinsky serves as SSAR representative to the MPLN, and he provided information on Joint Meeting policy changes. The most notable of these policies deals with number of presentations, no shows/cancellations, and symposia proposals for the Annual Meeting. Members of all societies agreed to the policies, which will be published separately.

Issues related to the SSAR webpage and online publishing were reported on by the Website Task Force (Lee Fitzgerald [Chair], Breck Bartholomew, John Matter, and George Pisani), which had been established in January by President Green to consider a vari-

ety of potential functions for the SSAR website. Current webmaster, George Pisani, was acknowledged for his dedicated service to the Society, but indicated his desire to be relieved of this position. To that end, the Society implemented a search for a new web coordinator.

The Society did not receive a report from the Joint SSAR/HL Task Force on Electronic Publishing (Brian Crother [Chair], Beth Dawson, Malcolm McCallum, and Laurie Vitt) in time to consider the issue at the meeting. The issue was discussed, however, with the most notable concern being the potential loss of revenue to the Society. This issue remained unresolved at the meeting, but the Board realized the necessity of coming to a decision as soon as possible.

Reluctantly, the Board noted the necessity of increasing dues for the coming year. Most membership categories are subject to a $10 increase, while maintaining the present cost of student memberships. Several new contributing member levels were outlined, to be reflected in the next dues notice, and it was hoped that the Society will see significant financial stability from this dues restructuring.

In one of his final public actions as SSAR President, David Green passed the engraved Presidential gavel, that treasured totem-of-office, to President-Elect Janalee Caldwell. Jan commented on the aesthetics of the item before closing the meeting at 1800 h.

—Respectfully submitted by John M. Matter, SSAR Secretary

New Policies for Presentations at Annual Meetings Approved by the Society, July 2002

Number of Presentations at Annual Meetings

Background.—Participation at the Joint Meetings of ASIH, AES, HL, SSAR, and Early Life History Section of AFS has increased over the past several years. As participation has increased the consequences of scheduling become more critical to the attendees at the Annual Meeting. Many members of the Societies have raised concerns over the length and timing of the meeting. The Meeting Planning Committee (MPLN) has struggled with constraining the length of the meeting, number of concurrent sessions, and ensuring that we do not schedule the same individual at the same time in different sessions. The MPLN has developed a policy that was approved at the 2002 Annual Business Meeting. The policy will be implemented beginning in 2003.

Policy.—Beginning at the 2003 Annual Meeting and continuing from then on, participants may submit only one abstract as a senior authored oral presentation for either an Invited Symposium or Oral Paper presentation. Participants may submit only one senior-authored poster presentation. In total, individuals shall only present one oral and possibly one poster presentation at Annual Meetings. Co-authorship via junior authorship is not limited. Notification of this policy will appear in the Call for Papers and on the ASIH, AES, HL, and SSAR web sites.

No Shows and Cancellations at Annual Meetings

Background.—Over the past several years the number of no-shows has begun to obstruct the flow of the meeting, disrupt sessions, and become a burden to the Societies. ASIH Governor Clark Hubbs raised this concern during the ASIH Business Meeting at the 2001 Annual Meeting at Pennsylvania State University. ASIH President Burr charged the MPLN to develop a policy to address this problem. This policy was approved at the SSAR Business Meeting and will be implemented beginning in 2003.

Policy.—If it is necessary to cancel a presentation (invited, oral, or poster) you must notify the designated member of the MPLN one month prior to the scheduled date of the Annual Meeting. For emergency circumstances, presentations must be cancelled 24 hours prior to the beginning of the first scheduled day of the Annual Meeting. Failure to do so shall result in a suspension of presentation privileges for 1 year.

Symposium Proposal Process

Symposia are important components of the Annual Meeting. These components provide useful information to the membership of participating Societies and contribute to a compelling and interesting experience. To provide a clear process the MPLN has developed the following set of guidelines.

Submission for consideration.—Proposals (3-page maximum) for consideration by MPLN should contain the following:

1. Symposium Title (or Topic)
2. Name of the Symposium Chair (phone number and e-mail address)
   a. Names of Associated Co-organizers
3. Information on topic and background
4. What benefit is the topic to the Society?
5. List of potential speakers and topics
6. Length of symposium (1/2 day, 1 day, etc.)—keep in mind the preference is for a one-day symposium with a likely maximum (in rare situations) of 2 days.
7. Sources of funding other than SSAR
8. SSAR funding requested and rationale (maximum per request = $1,500)

PROPOSALS DUE TO MPLN CHAIR by 1 March of the YEAR PRIOR to the meeting (i.e., 2004 Symposium Proposals are due 1 March 2003).

Responsibilities of the Symposium Chair(s):

1. Work with the participants to obtain titles and abstracts.
   a. Abstracts MUST be submitted to the SSAR meeting committee by the Annual Meeting abstract deadline using announced SSAR abstract submission procedures.
2. Develop and submit schedule for the symposium to the MPLN Chair by 1 March (year of the meeting). This includes the order, length (15 or 30 minutes), and scheduled times for all talks. Symposium Chair must provide the names of the moderators for the symposium at the same time.

MPLN Committee Review Process:

1. Proposals received by MPLN Chair and distributed to the MPLN for review by 5 March.
2. MPLN Chair collects comments and ranking of proposals by 30 March.
3. Consensus ranking redistributed to MPLN for review and comment.
4. MPLN selects two proposals for each Annual Meeting by 30 April.
5. All Symposia Chairs notified of acceptance or rejection by 30 April.

Journal of Herpetology: Notice of Mailing Error

The mailing labels for issue No. 1 of the *Journal of Herpetology* (mailed in April 2003) inadvertently had the subscriber's name omitted. This error occurred only for the U.S. subscribers. If you did not receive your journal, please contact your local mail sorter to see if your journal can be located. If it cannot be located, please contact the SSAR Publications Secretary (e-mail: ssar@herplit.com or phone 801-453-0489), and a replacement will be sent to you. The Society apologizes for this inconvenience.

NEWSNOTES

New Director of Sam Nobel Oklahoma Museum of Natural History

Ellen J. Censky, director of the Connecticut State Museum of Natural History at the University of Connecticut and long-time SSAR member (and current SSAR Board Member), has been named the new director of the Sam Noble Oklahoma Museum of Natural History at the University of Oklahoma. Censky will assume her new post May 1. Censky has served as director of the Connecticut State Museum of Natural History since 1998. The Sam Noble Oklahoma Museum of Natural History, one of the two largest natural history museums in the world associated with a university, opened the doors of its 198,000-square-foot, $44.5 million facility in May 2000. Prior to joining the Connecticut State Museum of Natural History, Censky served as chairman of the division of life sciences at the Carnegie Museum of Natural History in Pittsburgh from 1996 to 1998. She also served that museum as head of the amphibians and reptiles section as well as the section's assistant curator and collection manager. A 1979 graduate of the University of Wisconsin-Milwaukee, Censky earned her doctoral degree in biological sciences from the University of Pittsburgh in 1994.

Virginia R. Fitch Memorial Fund

Virginia R. Fitch passed away at home on 2 December 2002, at the Fitch Natural History Reservation near Lawrence, Kansas. The Fitch family and the University of Kansas Field Station and Ecological Reserves announce the establishment of the Virginia R. Fitch Memorial Fund for the purpose of honoring the memory of Virginia and her contribution to over 50 years of research and teaching at the Reservation. She contributed in many important ways to the field research that was conducted by her husband, Dr. Henry S. Fitch, many colleagues, and students. The Reservation is named in honor of the entire Fitch Family: Henry, Virginia, John, Alice, and Chester. The Fitch Nature Trail is named to specifically honor Henry and now, in memorial to Virginia, an open-sided covered shelter is planned to accommodate visiting classes of public and University students. This structure is to be built on the Reservation to facilitate public education involving nature, natural history, and ecology. This seems particularly appropriate considering Virginia's role not only as a contributor to many diverse research projects, but to the great hospitality she always provided to visitors to the Reservation.

Tax deductible (for U.S. residents) contributions may be made to the Virginia R. Fitch Memorial Fund in care of the Center for North American Herpetology (www.cnah.org), 1502 Medinah Circle, Lawrence, Kansas 66044, USA. Make checks payable to "CNAH Fitch Memorial."

Wanted: Photographs of Native North American Snakes

The North America Brown Tree Snake Control Team needs your help! We are a newly-formed organization whose mission is to keep brown tree snakes (*Boiga irregularis*) from establishing in North America. We desire to place photos of brown tree snakes and native North American snakes on our web site (www.NABTSCT.orgwww.NABTSCT.org) to aid the general public in brown tree snake identification. We need good quality photos (200– 600 dpi) of native North American snakes that can be used on our web site. Photographs, slides, CD's, or e-mail attachments (Jpeg files) can be sent. All photos, slides, and CD's will be returned. Please provide the name of the photographer for each photograph so that proper acknowledgment can be given. Send photos to: Scott E. Henke, MSC 218, Caesar Kleberg Wildlife Research Institute, Texas A&M University-Kingsville, Kingsville, Texas 78363, USA or as e-mail attachments to: scott.henke@tamuk.edu.

California Academy of Sciences Grants

Charles Stearns Grant-in-Aid for Herpetological Research

The Department of Herpetology is pleased to provide limited financial aid - mostly to cover round trip transportation and limited per diem expenses - to graduate students who wish to visit our collections to support research in systematics. Proposals should include a short—no more than one page—description of the research project, a budget, and a letter of support from the student's faculty advisor. Proposals are due on 15 October 2003, with notification by 1 December 2003. Grantees are expected to complete their Academy visit by 15 September 2004. Please call 415-750-7037 for further information. Send proposals to: Herpetology Research Grants, Department of Herpetology, California Academy of Sciences, Golden Gate Park, San Francisco, California 94118-4599, USA.

The CAS holdings are included in the Department of Herpetology database:

http://research.calacademy.org/herpetology/catalog/

Brett Stearns Award for Chelonian Research

The Department of Herpetology is pleased to provide limited financial aid—mostly to cover round-trip transportation and limited per diem expenses—to researchers who wish to visit our collections to support their work in chelonian biology. Preference will be given to graduate students. Proposals should include a short, one page description of the research project and a budget. In the case of graduate students, a letter of support from the student's faculty advisor is required. Proposals are due on 15 October 2003; notification will be made by 1 December 2003. Awardees are expected to complete their Academy visit by 15 September 2004. Please call (415) 750-7039 for further information.

Proposals should be sent to: Herpetology Research Grants, Department of Herpetology, California Academy of Sciences, Golden Gate Park, San Francisco, CA 94118-4599, USA.

The CAS chelonian holdings are included in the Department of Herpetology database: http://research.calacademy.org/herpetology/catalog/.

Gopher Tortoise Council Research Awards

Annually, the Gopher Tortoise Council awards the J. Larry Landers Student Research Award to the best student proposal submitted to the Council. Proposals can address undergraduate or graduate research concerning the biology of gopher tortoises (*Gopherus polyphemus*) or any other relevant aspect of southeastern U.S. upland habitat conservation. The amount of the award is variable, but has averaged US $1000.00 over the last few years.

The proposal should be limited to four pages and should include a description of the project, a concise budget, and a brief resume of the student applicant. Proposals should be submitted to Bob Herrington, Chair of Research Advisory Committee, Georgia Southwestern State University, Department of Biology, Americus, Georgia 31709, USA by 31 August 2003. Additional information can be found at <http://gophertortoisecouncil.org/>.

For SSAR Members in Indiana and Illinois

The Field Museum is conducting a survey of academic institutions, government agencies, and private organizations throughout Indiana and Illinois to determine how many teaching or research collections of fishes, amphibians, and reptiles exist in each state (preserved specimens only, not live animals). We believe that significant contributions can be made to the natural history of both Indiana and Illinois by reporting on the existence and status of small collections that are not well known by the scientific community. If your organization or institution maintains such a collection, please contact Jamie Ladonski (e-mail: jladonski@fieldmuseum.org) for more information on how your collection can be counted. Even if your department or office does not have such a collection, that information is valuable to our survey and we ask that you please contact us simply to note that fact. Please consider that collections might be at other locations if your institution has satellite campuses, field stations, or a similar network of offices.

MEETINGS

Meetings Calendar

12–16 August 2003—12th Ordinary General Meeting of Societas Europaea Herpetologica, St. Petersburg, Russia. Information: Natalia Ananjeva (e-mail: agama@NA4755.spb.edu).

3–6 September 2003—International Herpetological Symposium, 27th Annual Meeting, Houston, Texas, USA. Information: http://www.kingsnake.com/ihs/index.html.

15–20 November 2004—VI Symposium of Zoology, Havana, Cuba. Information:Executive Secretary: DrC. Daysi Rodríguez Batista (zoologia.ies@ama.cu) or www.geocities.com/zoologiacubana/simposio.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **Eli Greenbaum** or **Omar Torres-Carvajal**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can now be found at: http://www.herplit.com/contents.

Systematics of Gymnophthalmid Lizards

Phylogenetic relationships among members of the family Gymnophthalmidae are poorly known. The author performed a phylogenetic analysis of species of three genera (*Cercosaura*, *Pantodactylus*, and *Prionodactylus*) currently included in the tribe Cercosaurini, subfamily Cercosaurinae. The analysis was based on 61 external morphological characters; maximum parsimony criterion was used. Polymorphic characters were analyzed with the generalized frequency method. The author proposed a classification consistent both with the recovered history and a previously published hypothesis based on molecular data. *Pantodactylus* and *Prionodactylus* were considered junior synonyms of *Cercosaura*, and the latter genus was redefined to include 11 species.

Doan, T. M. 2003. A new phylogenetic classification for the gymnophthalmid genera *Cercosaura*, *Pantodactylus*, and *Prionodactylus* (Reptilia: Squamata). Zoological Journal of the Linnean Society 137:101–115.

Phenotypic Variation and Fitness of Hatchling Lizards

Variation in phenotype reflects variation in fitness; therefore, it is important to study the sources of phenotypic variation in order to understand the processes of natural selection. Phenotypes of hatchling reptiles are influenced by environmental factors, quantity or quality of yolk, and genetic contribution of the parents. The authors used eastern fence lizards (*Sceloporus undulatus*) to explore the effects of incubation moisture, maternal yolk investment, and clutch affiliation on phenotypes of hatchlings in the laboratory. Eggs from 28 clutches were distributed among wet and dry treatments, as well as a treatment in which yolk was removed. Hatchling performance traits were measured in the laboratory. Growth and survival under natural conditions were assessed by release and recapture of hatchlings in the field. The authors found that hatchlings from the wet treatment were bigger than those from the dry and yolk-removed treatments. However, only clutch affected hatchling performance and survival. These results suggest that variation in reptile phenotypes is strongly associated with clutch of origin.

Trematodes and Limb Deformities in *Rana*

Limb abnormalities in natural populations of amphibians might be caused by chemical pollution, UV-B radiation, predation, and parasites including trematodes. Disruption of spatial organization of cells in the limb bud is one of the mechanisms leading to outgrowth of limb deformities. These cells produce signaling molecules that set up the primary limb axes. The authors investigated how trematode cyst infection caused limb deformities in *Rana sylvatica* and *R. pipiens*. Infected and uninfected tadpoles were raised to metamorphosis and then examined for limb abnormalities. Deformities by surgical limb bud rotations also were performed for comparison. Trematode cercariae actively targeted hind limb bud regions and histological analysis showed that cysts induced abnormal tissue growth at early stages. Abnormalities resulting from trematode cyst-infestation closely resembled those induced by limb bud rotation, as well as those found in natural populations. These results suggest that cysts induce limb deformities in frogs by perturbing spatial organization of cells in limb buds. Because there is no direct evidence that chemical teratogens or UV-B radiation induce limb deformities in amphibians, trematode cysts might play a major role in causing limb abnormalities.

Dispersal of Viviparity in Fire Salamanders

Retention of ancestral states or lineage sorting in diverging populations are usual explanations for discordance between nuclear and mitochondrial DNA gene trees. However, this discordance may also result from gene introgression during reticulation events. Females of fire salamanders *Salamandra salamandra* either give birth to individuals that bypass the aquatic larval stage entirely (viviparity), or give birth to small aquatic larvae (ovoviviparity). Based on mtDNA sequences from 45 populations of fire salamanders in the Iberian Peninsula and data on nuclear markers from the literature, the authors performed a phylogeographic analysis to elucidate evolutionary processes acting on the populations and their influence on the evolution of viviparity. Two major discordances were found by plotting the geographic ranges defined by mtDNA and nuclear genes. Given that nuclear markers show high concordance in geographic distribution with life history, anatomy, and color pattern markers, the authors hypothesize that mtDNA markers reflect relatively deep history that has been obscured by geographic range expansion of the viviparous populations. This implies that nuclear genes have crossed contact zones fast and spread through the populations in contact producing admixture, whereas mtDNA has remained stationary resulting in a process of mtDNA capture. The authors suggested that demographic replacement via range shifts is the mechanism responsible for admixture of differentiated populations. Finally, they conclude that viviparity within fire salamanders arose only once.

Similarities Between Ovarian and Bidderian Oocytes

In vertebrate embryos, the gonadal primordium is colonized by the primordial germ cells and differentiates into either testis or ovary. Nonetheless, the anterior portion of the gonadal primordium fails to develop into testis in male bufonids resulting in an undeveloped ovary known as Bidder's organ. Bidderian oocytes grow and undergo vitellogenesis if testes are removed. The authors compared oogenesis between Bidder's organ and ovary in *Bufo marinus* by analyzing morphology and differentiated expression of the lamina-associated polypeptide 2 (LAP2). Isoforms of LAP2

are specific markers of frog germ and somatic cell differentiation. Bidderian oocyte growth was studied in male *Bufo marinus* for three months. Oocytes from Bidder's organ and ovary were examined with sodium dodecylsulfate polacrylamide gel electrophoresis and immunoblotting. Based on the *Xenopus laevis* staging of oogenesis, the authors classified *B. marinus* oogenesis into six stages. After orchidectomy, Bidder's organ became larger and more vascularized, and oocytes advanced to stages 2–3 of oogenesis. In addition, molecular similarities between ovarian and Bidderian oocytes were found. LAP2w, one of the isoforms of LAP2, was similarly upregulated in ovary and Bidder's organ. Moreover, large oocytes of both organs expressed LAP2w as the major isoform.

BROWN, F., E. M. DEL PINO, AND G. KROHNE. 2002. Bidder's organ in the toad *Bufo marinus*: effects of orchidectomy on the morphology and expression of lamina-associated polypeptide 2. Development, Growth, and Differentiation 44:527–535.

Evolution of Viviparity in Montane Reptiles

Transition from oviparity to viviparity in squamate reptiles offers an ideal model system to explore adaptationist hypotheses. The primary stimulus for the evolution of viviparity seems to be the invasion of cold climates. The strong correlation between viviparity and cold climates suggests that the selective force for viviparity involves incubation temperature. In an attempt to test the "cold-climate" hypothesis for the evolution of reptilian viviparity, the author performed laboratory and field experiments with the oviparous Australian three-lined skink *Bassiana duperreyi*. The effects of low-temperature incubation and brief retention at higher temperatures (to stimulate uterine retention) were investigated. Eggs incubated at higher temperatures completed development sooner, and "uterine retention" accelerated hatching to a greater degree in eggs that were then transferred to lower rather than higher incubation temperatures. The same pattern was observed for survival rate, running speed, and snout-vent length at one week; the latter was the only trait not affected by "uterine retention." In addition, incubation periods were longer in higher-elevation nests and in eggs that were not kept initially at uterine temperatures. These results support several predictions of the "cold-climate" hypothesis; however, other putative selective forces involved in the transition from oviparity to viviparity in reptiles need to be tested.

SHINE, R. 2002. Reconstructing an adaptationist scenario: what selective forces favor the evolution of viviparity in montane reptiles? American Naturalist 160:582–593.

Assessing the Conservation Status of Amphibian Assemblages

Amphibian global decline should be analyzed with quantitative data gathered through long time scales. Unfortunately, these data are usually scarce, which makes long-term population analyses difficult. The authors compared present and past densities and distribution ranges to evaluate the conservation status of amphibian populations from the Peñalara Natural Park in Spain. The study area is located between 1800–2430 m and contains an amphibian community of nine breeding species including *Salamandra salamandra*, *Bufo calamita*, and *Alytes obstetricans*. Larval density and distribution data of all species were obtained from 73 ponds during two time periods, 1982–1986 and 1999. A chi-square analysis was used to compare the observed ratio of extinctions to colonizations to an expected ratio of 1:1. Presence of a species in a pond was recorded only if there was evidence of reproduction of that species. The authors found no variation in species composition of the amphibian community in the park; however, a significant decrease in species per pond was observed. Larval densities of *A. obstetricans* and *B. calamita* decreased significantly; chytrid infection was detected in both species. In contrast, tadpole density of *Rana perezi* increased. Larval density also increased in ponds at high elevations, and decreased more in temporal than in permanent ponds. These results suggest that a decrease in number of species does not necessarily indicate a regional decline, and the actual general trend of a community might be obscured by expansions and declines occurring simultaneously. This is one of the few studies that report quantitative data on amphibian population decline at the community level.

Skeletal Development of the Spiny Softshell Turtle

Turtles have skeletal features that are very different from other tetrapods. Nonetheless, ontogenetic studies of their osteology are rare. Upon examination of 48 specimens, the author described in detail the osteology and skeletal development of the spiny softshell turtle *Apalone spinifera* and compared his results with published data of other turtles, as well as other reptilian taxa. Embryos were collected as eggs from a commercial turtle farm and incubated in the laboratory. Eggs were sampled at 3–4 day intervals, and developmental stages of embryos were determined with external morphological criteria. Data were obtained from skeletons and cleared and stained specimens. The author compared the chondrocranium of the spiny softshell turtle with chondrocrania of *Emys orbicularis* and *Caretta caretta*. In addition, differences and similarities in sequence and patterns of ossification between *A. spinifera* and *Chelydra serpentina* were described. For example, patterns of chondrification in the fore- and hindlimb of *A. spinifera* are similar to those of *C. serpentina*, but patterns of ossification in

both appendages are different. Finally, the author compared the ossification pattern in both species of turtles with those of *Lacerta* and *Alligator*. For instance, the first elements of the dermatocranium that ossify in *Apalone* and *Chelydra* are components of the skull table, whereas in *Lacerta* and *Alligator* palatal elements ossify first. These data have potential to provide phylogenetically informative characters.

Aggregation Behavior of Tadpoles of *Phrynomantis microps*

Severe climatic conditions, clumped food sources, mating advantages, and predation risk can lead to aggregation behaviors in many animal species. The author studied aggregation of tadpoles of *Phrynomantis microps* in the Comoé National Park, Ivory Coast. Water clarity and depth were estimated for each pond; tadpole size and age were also recorded. In addition, the standardized Morisita index was used to analyze dispersion of larvae with data from photographs. The author found that tadpoles form swarms during the day and are randomly distributed at night. Group size was significantly correlated with water clarity, water level, and age and size of tadpoles. However, water clarity explained most of the variability in aggregation size, which supports the idea that the selective force inducing aggregation behavior in *P. microps* larvae stems from visually hunting predators.

Estimating Maturity in Fossil Squamates

Accurate estimates of relative maturity in fossil vertebrates is critical for determining whether a series of specimens represents an ontogenetic series of one species or individuals of different species. Although body size is a potential indicator of maturity, it is not necessarily accurate and has sometimes led to mistaken observations. Terminal fusions between skeletal elements can be used as a size-independent criterion to estimate specimen maturity. The author examined the relationship between terminal fusions and sexual and skeletal maturity upon study of postnatal skeletal development of 21 extant species of lizards. Fusions were considered to be correlated with sexual maturity if their completion fell within 10% of average size at sexual maturity. Percentage of maximum size at which terminal fusions occurred was used to denote the relationship between fusions and skeletal maturity. The author found that terminal fusions were not reliable indicators of sexual maturity in all species examined. However, some fusions were good indicators in particular crown squamate clades. For example, the onset of fusion of the prootic and otoccipital ventrally correlated with sexual maturity in teiioids. More studies of the timing of terminal fusions in extant taxa are needed before we can use fusions as indicators of maturity in fossil squamates.

Effects of Climatic Change on Speciation of Palearctic Brown Frogs

Climatic changes since the Pliocene have allowed repeated events of allopatric speciation that resulted in present day species communities of the Northern hemisphere. With 20 species, *Rana* (water frogs and brown frogs) is the most specious genus among Western Palearctic amphibians and represents an ideal taxon for testing vicariance hypotheses. In this study, the authors tested the hypothesis that recent climatic oscillations were responsible for radiation of Western Palearctic brown frogs. They performed phylogenetic analyses of all species of brown frogs using mitochondrial and nuclear DNA sequence data. Neighbor joining, maximum parsimony, maximum likelihood, and Bayesian analysis were used as methods of phylogenetic inference. A molecular clock was calibrated and used to date speciation events. All phylogenetic analyses resulted in the same topology consisting in a basal radiation into five lineages. The authors found that the basic radiation among brown frogs can be dated to the post-Messinian (ca. 4 mya). The *Rana temporaria* species group split into five lineages 3.0 mya, the Anatolian lineage radiated around 2.4 mya, and *R. temporaria* split into two lineages about 1.0 mya. These estimates of major speciation times are congruent with post-Messinian climatic fluctuations, which suggests that radiation of Western Palearctic brown frogs was triggered by the onset of glaciers with cycles of repeated cold and warm periods.

VEITH, M., J. KOSUCH, AND M. VENCES. 2003. Climatic oscillations triggered post-Messinian speciation of Western Palearctic brown frogs (Amphibia, Ranidae). Molecular Phylogenetics and Evolution 26:310–327.

ZOO VIEW

Sadly, two zoo herpetologists have died prematurely after long struggles with medical problems: Sean McKeown and John McLain. Both were visionaries, thoroughly committed to conservation and the captive management of threatened amphibians and reptiles. They will be missed by their friends in the zoo community.

For two decades beginning in 1975, Sean McKeown was the herpetological curator at the Honolulu Zoo and later at the Chaffee Zoo in Fresno, California. McKeown published many papers on geckos, especially day geckos of the genus *Phelsuma*. His 1993 book "The General Care and Maintenance of Day Geckos" is the standard guide covering this diverse group.

His first book, published in 1978, was on Hawaii herpetofauna: "Hawaiian Reptiles and Amphibians." His second, written 18 years later and entitled "Field Guide to the Reptiles and Amphibians in the Hawaiian Islands," documented the establishment of alien species: red-eared sliders, Jackson's chameleon, and Madagascar day geckos. Sean was concerned about the possibility of accidental releases of the brown tree snake from Guam into Hawaii and was a member of the "Brown Tree Snake Control Group," an active assemblage of conservationists who implemented detection and removal plans.

Sean was a fervent supporter of the ecosystem approach for managing and displaying reptiles and amphibians in zoos. He always felt that herps should be exhibited in naturalistic settings. In 1989, he documented the first captive breeding of the Madagascar ground boa in North America from long-term captive adults.

Sean loved tortoises and wrote papers on managing and breeding them in captivity, such as those on the reproductive biology of the Asian brown and Angonoka tortoises at the Honolulu Zoo in 1982. The next year, the Zoo received the AZA's Edward H. Bean Award, given annually for the most prestigious accomplishment in the captive management and breeding of zoo animals, for Sean's efforts in reproducing the Angonoka tortoise. He was a consultant for the Republic of the Seychelles Conservation Department to assist in developing a captive tortoise colony. Sean died on 11 July 2002 after a heart transplant roughly two years earlier and is survived by his wife Wendy and two daughters. See Breese (2002. Bull. Chicago Herpetol. Soc. 37:152) for an expanded description of his importance to zoo herpetology. An obituary also appeared in *HR* earlier this year (see Chun and Beaman 2003. Herpetol. Rev. 34:9–11).

John McLain had been battling liver cancer for over a year and succumbed on 7 December 2002. He was past chair of the Snake Advisory Group of the American Association of Zoos and Aquariums (AZA) and former Curator of Herpetology at the San Antonio Zoo in Texas. John began his zoo career as a keeper, and later assistant supervisor at the Houston Zoo in the 1980's under curator Hugh Quinn and director John Werler. His interest in snakes, especially boas and pythons, was well known in the zoo community and he cared for one of the finest collections of these ophidians in the world (see McLain. 1982. Notes on boid reproduction at the Houston Zoological Park, pp. 248–264. Proc. 6th Int. Herpetol. Symp. Captive Propagation Husbandry). The Houston Zoo had a magnificent collection of boas and pythons: all three Madagascan boas, Angolan dwarf python, Calabar boa, white-lipped python, black-headed python, ringed python, Panamanian woodsnake, all of the Pacific boas, Argentinian boa, black python, and many insular Caribbean forms. As Species Survival Plan (SSP) coordinator for Dumeril's ground boa (*Acrantophis dumerili*), he started one of the first reptile SSPs for the AZA.

John was among the astounding number of zoo herpetologists who worked in Houston over the years (the late Joe Laszlo, Tim Jones, John Banks, Ardell Mitchell, Bern Tryon, R. Andrew Odum and Karl Peterson), and later held curatorial posts. No other zoo can duplicate this placement of so many former employees on this administrative level.

John had a sardonic wit and it was always fun to listen to him assess the state of the world with his unique brand of humor. He is survived by his wife Judy and daughter Kelsea.

Don Nichols is a pathologist in the Department of Pathology at the National Zoological Park in Washington, DC. He has done research on a number of herps: use of methohexital sodium as an anesthetic in two species of colubrid snakes, radiation therapy of a malignant chromatophoroma in a yellow rat snake, perivertebral mineralization in a giant tree frog (*Phyllomedusa bicolor*), gout in giant day geckoes, infectious diseases of amphibians, neoplasia in snakes, isolation and experimental transmission of a reovirus pathogenic in ratsnakes, and paramyxovirus infection in caiman lizards (*Dracaena guianensis*). He has assessed the health status of cricket frogs (*Acris crepitans*) and environmental quality in areas of abundant and reduced populations as well as forms and prevalence of intersexuality and effects of environmental contaminants on sexuality in this taxon.

Don has also focused on brown tree snakes (*Boiga irregularis*) in an attempt to develop a biological control on Guam with studies on reference hematologic and plasma chemistry values, fatal mycotic dermatitis, and pathology of experimental ophidian paramyxovirus infection.

Several years ago, Don described his experiences to me as he tracked down the elusive chytrid organism responsible for amphibian mortality in wild and captive populations. It is an intriguing herpetological detective story which would be of interest to any sleuth so I asked him to document his experiences in the following article.

—James B. Murphy, Section Editor

Herpetological Review, 2003, 34(2), 101–104.

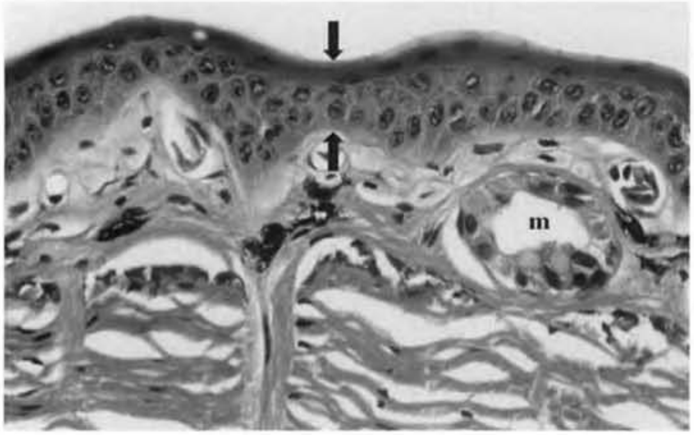
Tracking Down the Killer Chytrid of Amphibians

DONALD K. NICHOLS, DVM DACVP
Department of Pathology, National Zoological Park
3001 Connecticut Avenue, NW, Washington, DC 20008, USA
e-mail: nicholsd@nzp.si.edu

Most species of fungi in the Phylum Chytridiomycota (chytrids) are saprophytic decomposers of organic matter. Some are known to be parasites of other fungi, plants, or invertebrate animals. Until recently, no chytrids had ever been recognized as pathogens in vertebrate animals. However, one chytrid species, *Batrachochytrium dendrobatidis*, has now been shown to cause fatal skin disease in frogs and toads. This disease has had devastating impacts on captive collections of amphibians and is believed to be a significant factor in the declines of many wild anuran populations. The following is an account of the role I played in the discovery of this novel amphibian pathogen.

After completing a residency in veterinary pathology at the National Zoological Park (NZP) in 1987, I accepted a position as a staff pathologist at the National Institutes of Health (NIH) in Bethesda, Maryland. My work at NIH mostly involved rodents and other standard laboratory animals. However, my primary professional interests continued to be the diseases of exotic animals and wildlife, especially reptiles and amphibians. Therefore, while employed at NIH, I also had a part-time consulting pathology service for several zoos and other institutions that housed non-domestic animals.

It was as a consulting pathologist that I received three dead formalin-fixed California Arroyo Toads (*Bufo microscaphus*



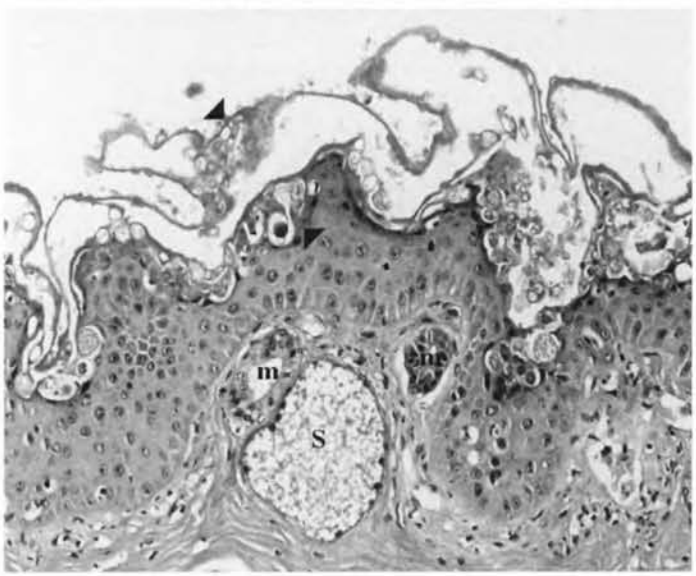


FIG. 1A (top). Photomicrograph of normal skin from a California Arroyo Toad (*Bufo microscaphus californicus*). The epidermis (between arrows) is three to four cell layers thick and only the outermost layer is keratinized. A circular mucous gland (m) is located in the dermis just beneath the epidermis. Magnification is 200x. 1B (bottom). Photomicrograph of skin from an affected California Arroyo Toad. The epidermis is diffusely thickened, especially the keratinized layers (between arrowheads). Within the keratinized layers are numerous variably-sized round nucleated organisms. Two mucous glands (m) and one serous gland (S) are located beneath the epidermis. Magnification is 120x.

californicus) in early November 1991. These animals had been part of a captive colony consisting of approximately 120 animals kept at the University of California-Santa Barbara. A disease outbreak of unknown cause had already led to the deaths of approximately 60% of the toads in this colony during the two months before the carcasses were sent to me. On histologic examination of all major organs from these toads, I discovered that all three had a skin disease characterized by moderate to marked thickening of the epidermis, especially the outer keratinized layers (Figs. 1A–B). Within these lesions (primarily in the keratinized layers) were numerous microscopic single-cell eukaryotic organisms unlike anything I had ever seen before (Figs. 1B, 2). Other organs from the toads did not contain any significant lesions. Therefore, I concluded that the skin disease was responsible for the deaths of the toads by interfering with normal skin function, which in amphibians includes maintenance of hydration and electrolyte balance, thermoregulation, and even respiration to varying extents. I also concluded that the microscopic organisms were most likely the cause of the skin lesions.

I then began a quest to determine exactly what those microorganisms were; it would eventually take more than five years to satisfy my curiosity. As the first step in this process, I performed a thorough search of the published literature and I did not find any reports of similar organisms affecting the skin of amphibians or any other animal.

My initial impression from examining standard histology slides of the toad skins was that the organisms most closely resembled sporozoan-type protozoa. Therefore, I next showed the slides to an expert on protozoal parasites, Dr. Chris Gardiner, who was stationed at the Armed Forces Institute of Pathology (AFIP) located in the Walter Reed Army Medical Complex in Washington, DC. Following his suggestions, I had additional histology slides prepared and stained with several different "special stains" (e.g., Gram, acid-fast, and periodic acid-Schiff). We also examined the organisms using transmission electron microscopy (TEM). After examining all this material, Dr. Gardiner concluded that the organisms definitely were not protozoa; he suggested that they were probably algae or fungi.

I then showed the histology slides and photographs from the TEM examinations to Dr. Maria Faust. She is an expert on algae at the Smithsonian's National Museum of Natural History. Her conclusion was that the organisms definitely were not algae, but were probably fungi or protozoa.

At this point, I concluded that the organisms must be some type of fungi. However, their morphology and staining characteristics in the special stains were unlike any fungal pathogens commonly encountered in human or veterinary medicine. To try to determine what kind of fungi they were, I next traveled to the National Library of Medicine located on the NIH campus to consult textbooks on the morphology of fungi by TEM. Unfortunately, the samples that I had from the arroyo toads had undergone some post-mortem decomposition and had been fixed in formalin, which is not an ideal fixative solution for TEM. Thus, these samples had many artifacts in them that interfered with interpretation. Also unfortunate was the fact that entire arroyo toad colony had died by this time, making it impossible to collect fresh samples and fix them in a proper TEM fixative.

The TEM examinations did clearly demonstrate that at one stage of development, the organisms consisted of cystic structures containing flagellated spore-like forms (Fig. 3). However, no types of fungi had flagellated spores in the TEM textbooks that I consulted; much later I realized that the fact that all of these books were written in the mid-to-late 1980's was very important (see footnote below).

At this point, I still had no idea what the organisms were; I could only say what they were not: fungi, algae, protozoa, animals, plants, or bacteria. Because I could not obtain further samples for study, I decided to give up trying to identify them for a while.

In the fall of 1991, I accepted a staff position as Associate Pathologist and returned to NZP. Shortly thereafter, I performed a retrospective search of the pathology files at NZP to see if any similar organisms had been seen in amphibians from the zoo's collection. My search revealed three cases of skin disease in frogs associated with organisms that closely resembled those in the ar-

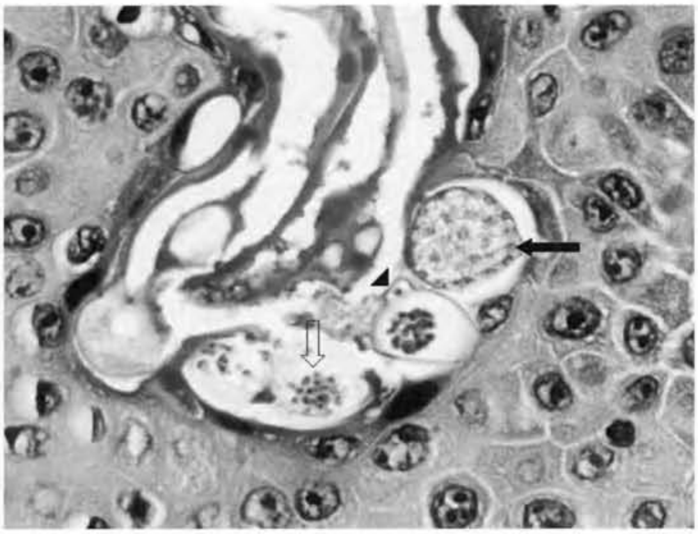

FIG. 2. Higher magnification of Fig. 1B demonstrating three forms of the organisms in the epidermis at the junction between the non-keratinized and keratinized layers. One form has multiple nuclei separated by lacey cytoplasm (solid arrow). Multiple spore-like forms are present in a cystic structure; this cyst has a flat papilla (arrowhead) through which the spores are released. A clump of discharged spores (open arrow) is also present. Magnification is 480x.

royo toads: a White's Tree Frog (*Litoria caerulea*) that died in 1988, an Ornate Horned Frog (*Ceratophrys ornata*) that died in January 1990, and another *L. caerulea* that died in September 1990. I then retrieved archived tissue samples from these cases and had the same special stains done on them as were done before; results were the same as with the arroyo toad samples. The results of TEM were also similar to before, including the artifacts that prevented definitive identification of the organisms.

Because this disease had occurred in NZP collection animals on at least three separate occasions, I reasoned that it might occur again. Over the next several years, whenever an amphibian was presented for necropsy, I instructed the pathology residents to collect numerous samples of skin for histologic examination. If I was asked why, my reply was "Because I am looking for something and I don't really know what it is."

By the spring of 1996, I had just about given up on finding the organisms again. Therefore, I decided that I would present the information that I had on this new amphibian disease at the annual conference of the American Association of Zoo Veterinarians (AAZV) that year. While preparing my abstract for the meeting, I stumbled across a textbook titled *Handbook of Protoctista* (Margulis et al. 1990). This 900+ page book contains detailed descriptions (including photographs of morphology by TEM) for each group of organisms in the Kingdom Protoctista (aka Kingdom Protista).

In this book were several phyla of aquatic organisms that produce flagellated spores and were originally classified as fungi; these so-called "zoosporic fungi" consisted of the Phyla Chytridiomycota, Hyphochytridiomycota, Oomycota, Labyrinthulomycota, and Plasmodiophoromycota. The morphology of the amphibian pathogens resembled those of these "zoosporic fungi" closely enough that I felt confident in calling them "aquatic fungal-like protists" in the paper that I presented at the 1996 AAZV meeting (Nichols et al. 1996). However, the artifacts in the TEM material from the organisms still prevented determination of which "zoosporic fungi" they were.

The event that finally allowed me to determine exactly what these organisms are came in the Fall of 1996. In September that year, an outbreak of the skin disease began in the NZP collection animals. Over the next several months, this outbreak resulted in the deaths of 24 juvenile Blue Poison Dart Frogs (*Dendrobates azureus*), 4 Green-and-Black Poison Dart Frogs (*D. auratus*), 3 White's Tree Frogs, and 1 Ornate Horned Frog. Once we realized that there was an ongoing outbreak, we were able to collect skin samples from freshly dead frogs and place them in a proper fixative solution for TEM. Morphology of these organisms by TEM closely resembled those in the Phylum Chytridiomycota.

Dr. Allan Pessier, our pathology resident at the time, then ran an Internet search and found the webpage of one of the few chytrid experts in the world, Dr. Joyce Longcore at the University of Maine. We sent her photographs of our TEM findings and she confirmed that the morphology of the organisms was consistent with a chytrid species (Pessier et al. 1999). We then sent her fresh skin samples from an affected *Dendrobates azureus* and she was able to isolate the organisms into culture. She also isolated the identical organism from an infected *D. auratus*, and later from a *Litoria caerulea*. Subsequent studies of the organisms by Longcore confirmed that not only was this a new chytrid species but it represented a novel genus as well. We eventually named this organism *Batrachochytrium dendrobatidis*, which has its roots in Greek and translates roughly as "frog chytrid of dendrobatids" (Longcore et al. 1999).

While Allan, Joyce, and I were characterizing this organism and the disease it causes, I received word in 1997 that other groups had seen something very similar associated with marked declines in wild populations of anurans in Australia and Central America. Drs. Rick Speare, Alex Hyatt, and Lee Berger headed the group in Australia and the group working on the disease in Central America consisted of Drs. Karen Lips, Peter Daszak, Andrew Cunningham,

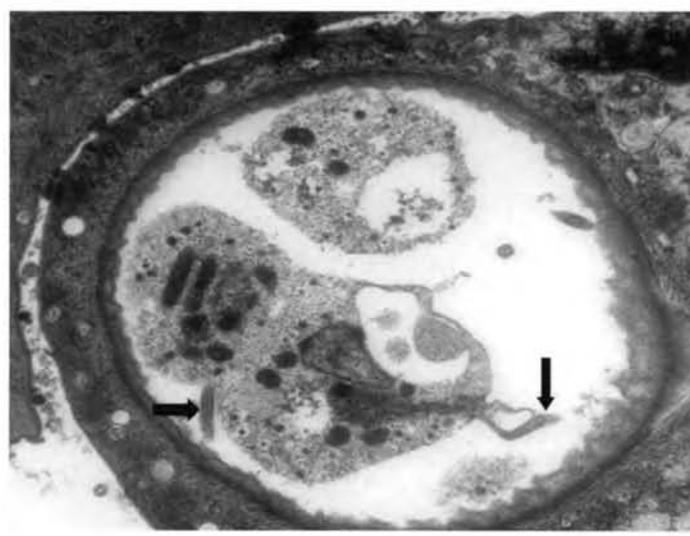

FIG. 3. Transmission electron photomicrograph of the epidermis from an affected California Arroyo Toad. Within one epidermal cell, there is a thick-walled cyst-like structure with an undulating interior border. Three round spores are present within the cyst (the cell membranes of two of these spores overlap). Flagella (arrows) are present, indicating that the spore stages of the organisms are aquatic. Magnification is 27,308x.

and David E. Green. My correspondence with these groups revealed that they were indeed seeing an identical disease and this was associated with organisms that appeared to be very similar to the chytrids we were studying. Although these groups had not been able to culture the organisms, they had concluded that the organisms were chytrids through the use of TEM and molecular genetics (Berger et al. 1998). Suddenly the interesting disease that I had been seeing in captive amphibians had taken on much more importance!

Cutaneous chytridiomycosis appears to be an emergent fatal disease of both captive and wild amphibians. Many now consider it to be one of the leading causes for the global declines of wild amphibian populations (Berger et al. 1998; Bosch et al. 2001; Daszak et al. 1999; Lips 1999; Ron and Merino 2000). Within the last six years, this disease has been recognized as the cause of death of captive and/or wild amphibians in Australia, New Zealand, North America, Central America, South America, Africa, and Europe (Speare and Berger 2002). The reasons for the apparent sudden appearance of this disease in so many areas of the world remain subjects for conjecture and ongoing research.

Joyce Longcore has more than 70 isolates of chytrids from various outbreaks of amphibian chytridiomycosis and from multiple amphibian species. So far, all of these have been *Batrachochytrium dendrobatidis*, indicating that this single chytrid species is responsible for causing the disease worldwide. Molecular studies are underway to determine how much genetic drift has occurred among the different isolates in an effort to establish when the organisms might have been dispersed and their geographical origin. Other researchers are looking at preserved amphibian specimens in museum archives to determine when chytrids first appeared in various amphibian populations. Efforts to develop sensitive tests for detecting chytrid infections in amphibians are also underway.

Early reports that cutaneous chytrid infections were fatal to amphibians and were a cause for declines in wild populations were met with some skepticism. In response to this, we conducted several experiments in our lab at NZP to prove the pathogenicity of the chytrids. We have consistently been able to infect recently metamorphosed dendrobatid frogs of three different species and these infections have resulted in 100% mortality (Nichols et al. 2001; Nichols and Lamirande, unpubl. data).

In other studies, we have shown that dendrobatid tadpoles can be infected and remain asymptomatic for as long as 87 days, but then 100% of them die at the last stages of metamorphosis or shortly thereafter (Lamirande and Nichols 2002). We have also developed treatment protocols that can be used to cure chytrid infections in captive frogs (Nichols and Lamirande 2000) and tadpoles (Nichols and Lamirande, unpubl. data).

Much remains to be discovered about *Batrachochytrium dendrobatidis* and the factors that influence the development of chytridiomycosis in amphibians. Other chytrid-related research that I hope to be able to conduct someday includes looking at the effects of temperature on the disease, determining how long the chytrids can survive in environments without the presence of amphibian hosts, and determining exactly what causes chytrid-infected amphibians to die.

Footnote.—Organisms in the Phylum Chytridiomycota were originally classified as unique types of fungi. In the early 1980s, taxonomists agreed that these organisms, along with the other phyla of "zoosporic fungi" should be removed from the Kingdom Fungi and placed in the Kingdom Protista. Molecular DNA studies conducted in the late 1980s and early 1990s resulted in the Phylum Chytridiomycota being placed once again in with the fungi. The other phyla of "zoosporic fungi" remain classified as organisms other than fungi.

In 1991–92, when I was looking for information on fungal morphology by TEM, I consulted textbooks published in the mid-to-late 1980s. Chytrids were not included because they were not considered to be fungi at the time the books were written. Ironically, if I had used older "out-of-date" texts on fungi, chytrids would have been included, and thus I might have saved myself five years of frustration in trying to identify the organisms.

The Black Racerunner (*Cnemidophorus nigricolor* Peters, 1873) in Los Roques Archipelago, Venezuela

JAMES M. WALKER*
and
DOUGLAS D. RHOADS
Department of Biological Sciences, University of Arkansas
Fayetteville, Arkansas 72701, USA

Corresponding author; e-mail: jmwalker@mail.uark.edu

The name *Cnemidophorus lemniscatus nigricolor* had been applied to the black race runner of numerous Caribbean islands (Burt 1931) for nearly 60 years when Sites et al. (1990) and Vyas et al. (1990), without explanation, used the original combination *C. nigricolor* Peters, 1873 for this taxon in their genetic study of the hybrid origin of two parthenogenetic members of the *C. lemniscatus* complex. Subsequently, Wright (1993) and Paulissen and Walker (1994) also used the name *C. nigricolor* for lizards from islands included in the range of this form by Burt (1931); however, they did not specifically discuss issues relating to the status of the taxon.

Our major objective is to recommend formally that the name *C. nigricolor*, based on four cotypes from "Insel Gruppe Los Rocques, im Norden von La Guayra, Venezuela" (from Peters 1873, in Burt 1931), be applied to a species comprising all insular populations subsequently found to be diagnosed by the characters summarized herein. To facilitate the evaluation of other insular populations for possible allocation to *C. nigricolor*, we present a modern diagnosis, description, and analysis of variation based on a large sample of this species from Grand Roque, the largest island in Los Roques Archipelago. We also supplement Paulissen and Walker's (1994) observations on the natural history of the species.

Los Roques Archipelago National Park comprises over 50 islands and 200 keys situated above coral reefs around a central lagoon located between 11°42'–12°04'N and 66°30'–67°00'W in the Caribbean Sea (ca. 166 km north of La Guaira on the central coast of Venezuela). Annual climatic means for the archipelago are 28.9°C temperature, 84% humidity, and 271 mm of precipitation. Selected characteristics of islands and keys in the archipelago from which we report *C. nigricolor* are included in Table 1.

The dorsal pattern in *C. nigricolor* consists of linear series of spots apparently derived from the four pairs of primary stripes (= ventrolaterals, laterals, dorsolaterals, and paravertebrals) and 2–3 secondary stripes (= middorsals) between the paravertebrals characteristic of certain mainland South American populations of *C. lemniscatus*. Color pattern descriptions were facilitated by five color photographs of *C. nigricolor* in situ taken by one of us (DDR) in Los Roques Archipelago.

We used counts of 11 meristic characters and one ratio for 45 specimens of *C. nigricolor* from Grand Roque Island and 71 specimens of *C. lemniscatus* from two sites in Suriname. All lizards examined bear University of Colorado Museum (UCM) numbers. Characters examined, including some used in studies of *Cnemidophorus* by Duellman and Wellman (1960), Duellman and Zweifel (1962), Walker (1981), and those considered for the first time in this study, are granules (scales) around midbody (GAB), granules from occiput to rump (OR), ratio x 100 of the granules around midbody to the granules from occiput to rump (GAB/OR), femoral pores combined (FP), subdigital lamellae of longest toe of left pes (SDL), right and left supraocular scales combined (SO), circumorbital scales combined (COS), lateral supraocular granules combined (LSG), parietal scales (PS), mesoptychial scales (posterior most transverse row of enlarged scales of the mesoptychium) (MS), scale rows anterior to the edge of the posterior gular fold (Burt 1931) (SAG), and scales bordering the outer edges of the parietal scales between the circumorbital series on each side (SBP).

Individuals of *C. lemniscatus* and *C. nigricolor* were measured to the nearest mm in snout–vent length (SVL). Clutch size for each gravid female of *C. nigricolor* was based on counts of either vitellogenic follicles >3 mm in diameter or oviductal eggs. Means, standard errors, and Duncan's Multiple Range Tests for statistical significance ($P = 0.05$) were processed using SAS software administered by the University of Arkansas Computing Services.

Diagnostically, *C. nigricolor* differs from *C. lemniscatus* as characterized by Cole and Dessauer (1993) in having gray dorsal and ventral surfaces and longitudinally arranged gray-white dorsal spots in hatchlings and juveniles, mostly black dorsal and ventral surfaces in adults, granular postantebrachial scales on the posterior surface of each forearm, small scales at the edge of the gular fold, circumorbital scale series usually ending posterior to the midpoints of the third supraocular scales, eight rows of ventral scales, a pointed scale (= anal spur) on each side of the cloaca in males, five parietal scales, moderately high mean numbers of granules around midbody (103.0 ± 0.69) and granules from occiput to rump (221.7 ± 1.29), unusually high mean number of femoral pores (54.1 ± 0.40), and maximum body length of 101 mm.

TABLE 1. Selected characteristics of the parts of Los Roques Archipelago, Venezuela, known to be inhabited by *Cnemidophorus nigricolor*.

Island or Key	Area of Island	Part of Archipelago	Permanent Settlements?	Source
Grand Roque	4.0 x 0.8 km	NE of Lagoon	Yes - Villages	T. Maslin; Burt (1931); this study
Francisqui	Tiny by comparison	NE of Lagoon	No (only visitors)	this study
Crasqui	Tiny by comparison	NE of Lagoon	No (only visitors)	this study
Noronquises	Cluster of tiny keys	NE of Lagoon	No (only visitors)	this study
Cayo Sal	Sand spit ± 30 m wide	S of Lagoon	No (only visitors)	this study

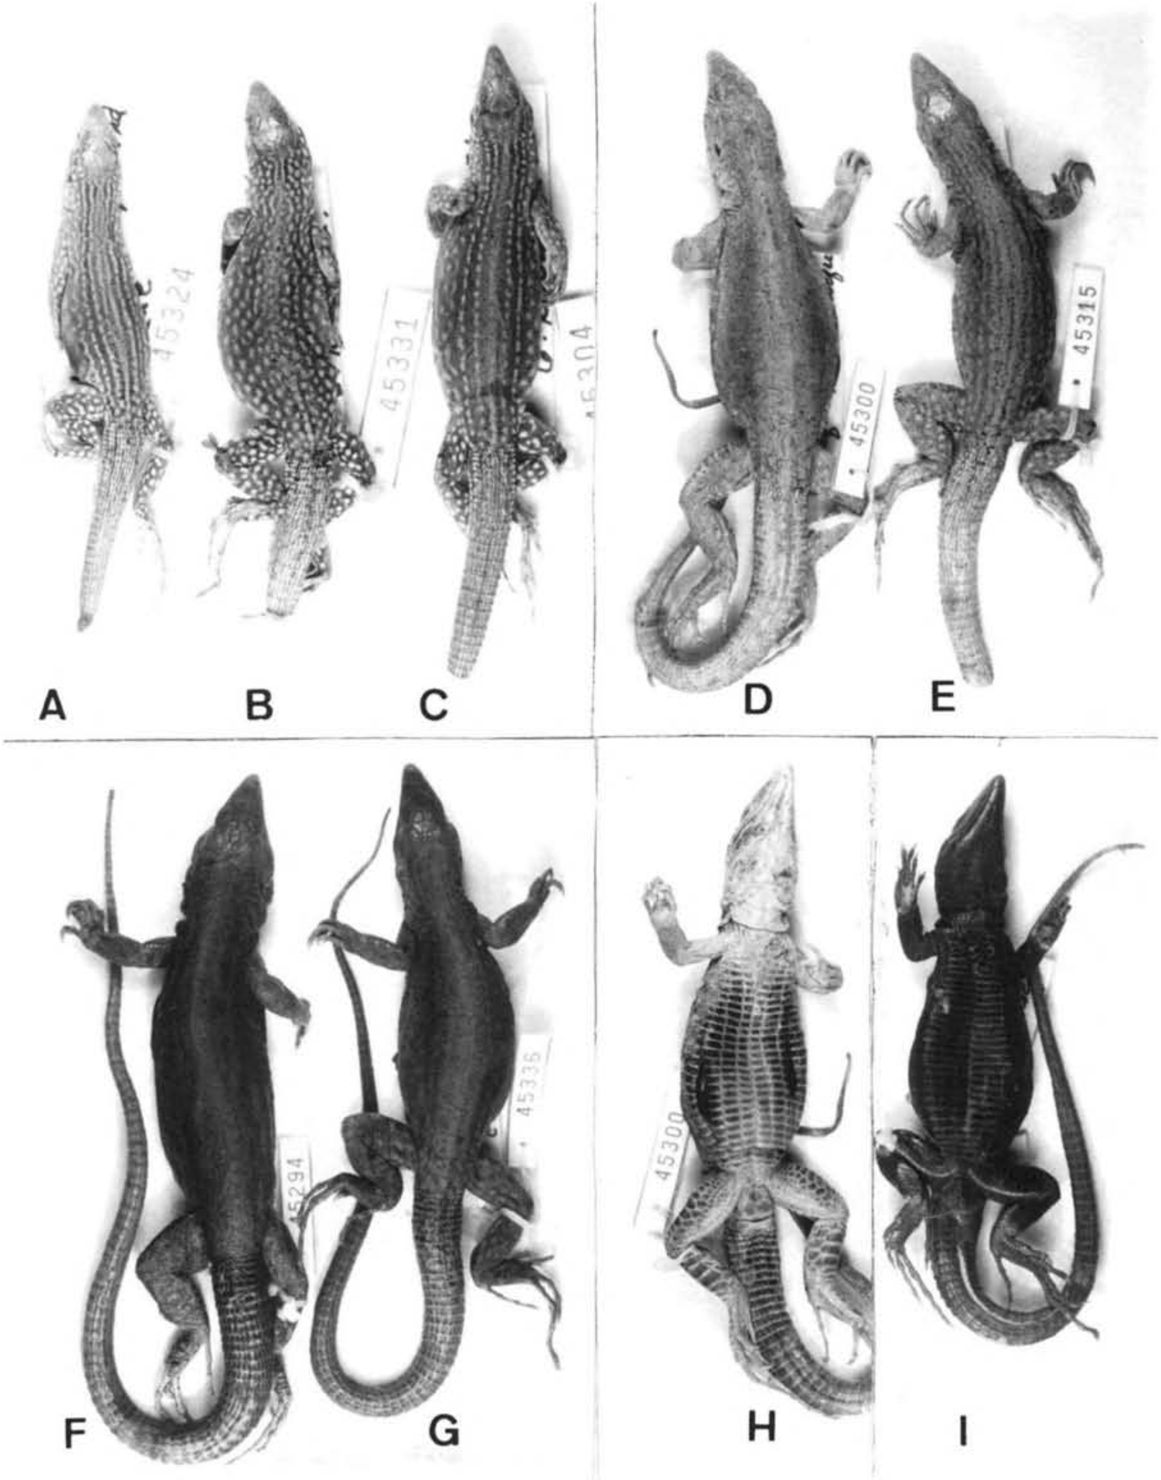

FIG. 1. Color pattern variation in females (A, UCM 45324, SVL 47 mm; B, UCM 45331, SVL 55 mm; C, UCM 45304, SVL 57 mm) and males (D, H, UCM 45300, SVL 91 mm; E, UCM 45315 SVL 84 mm; F, UCM 45294, SVL 101 mm; G, UCM 45336, SVL 86 mm; I, UCM 45314 SVL 90 mm) of *Cnemidophorus nigricolor* from Grand Roque Island, Venezuela.

Descriptively, in *C. nigricolor* small mesoptychial scales precede the most posterior row of enlarged scales on the gular fold (2–5 rows in 19 females and 2–6 rows in 26 males); the supraocular scales seldom vary from 4-4 (44 of 45 specimens), there are usually five parietal scales on the dorsal surface of the head (13 of 19 females and 23 of 26 males), and the circumorbital scale series medial to the supraocular scales are short (to middle of fourth supraoculars in 10 of 19 females and 21 of 26 males). Compared with *C. lemniscatus* and its derivatives (Cole and Dessauer 1993; Markezich et al. 1997) the species has equivalent, somewhat higher, or somewhat lower means and ranges of variation for the meristic variables GAB, OR, FP, SDL, SO, COS, LSG, PS, MS, SAG, and SBP and the GAB/OR ratio (Table 2).

Hatchlings and juveniles of *C. nigricolor* have medium (Fig. 1A) to dark gray or pewter (Fig. 1B, C) dorsal and ventral surfaces, numerous small white spots on the hind limbs (Fig. 1A–C),

TABLE 2. Data reductions for a sample of *Cnemidophorus nigricolor* from Grand Roque Island, Venezuela, and two samples of *C. lemniscatus* from Suriname. Numbers are means ± SE, followed by ranges, with sample size in parentheses (abbreviations for characters are given in the text).

Character	*nigricolor* Grand Roque	*lemniscatus* Baboensanti	*lemniscatus* Bigi Poika

and longitudinal series of white spots and/or middorsal stripes or their fragments (Fig. 1A–C). Both sexes develop melanistic dorsal and ventral colorations except for the dark gray to brown areas of the middorsal region, dorsal surface of tail, and scales around the femoral pores (Fig. 1F, G, I). Black to dark brown pigment initially develops on the sides of the body (in a "peppered" distribution in females; Fig. 1D, E) and ventral surfaces (Fig. 1H). Faint evidence of the middorsal stripes might persist even in the largest adult males.

Among 19 females of *C. nigricolor* (SVL 47–77 mm) from Grand Roque Island are 11 individuals of SVL 47–76 mm that retain either a pattern similar to that of juveniles or have only slight evidence of ontogenesis. Also present are eight females of SVL 67–77 mm that show 60–75% completion of pattern development (based on the final pattern attained by males). Pattern ontogenesis is initiated in most females at SVL 67–69 mm; however, there were too few large adult females in the UCM sample to determine whether they develop the same color pattern as large males (Fig. 1F, G, I).

Among 26 males of *C. nigricolor* (SVL 38–101 mm) from Grand Roque are eight individuals between SVL 38–67 mm that had either retained their juvenile pattern or undergone very little pattern ontogenesis. The largest male with delayed pattern development and a gray rather than black dorsal coloration is UCM 45300 (SVL 91 mm; Fig. 1D); two additional adult males of SVLs 76 mm (UCM 45322) and 84 mm (UCM 45315; Fig. 1E) are similarly patterned. The other 14 males in the sample between SVLs 76–101 mm exhibit complete to nearly complete color pattern ontogenesis.

Nine gravid females in the UCM sample of *C. nigricolor* from Grand Roque Island collected on 3 July 1971 have a mean SVL of 70.6 ± 2.07 mm, mean clutch size of 1.3 ± 0.16 eggs, and clutches of one egg in females of SVL 57, 68, 69, 69, 74, and 77 mm and two eggs in females of SVL 69, 76, and 76 mm. The presumed missing age class of large females of *C. nigricolor* that would have been included in the SVL 80–101 mm range of 46% of the males in the UCM sample most likely reflects collecting bias. The size of the smallest gravid female with one egg of >10 mm in diameter (UCM 45304; SVL 57 mm) indicates that *C. nigricolor* is similar to the recently described derivative of *C. lemniscatus*, namely *C. arenivagus* of the Peninsula de Paraguana, Venezuela (Markezich et al. 1997), that is early-maturing and likely multiple-brooded in its tropical habitat. Most rainfall in Los Roques Archipelago occurs between September and January; however, the presence of gravid females in the UCM July sample of *C. nigricolor* indicates that reproduction is not limited to the wet season.

Cnemidophorus nigricolor is an ubiquitous species in sandy beach strands frequented by tourists on Grand Roque Island and the much smaller land masses Francisqui, Crasqui, Noronquises, and Cayo Sal (Table 1). On Francisqui, Noronquises, and Cayo Sal this species responded to the presence of humans by emerging from nearby sea purslane or red mangrove vegetation to vie for handouts. Lizards would often approach to within a few inches from a person to eat bits of apple and lettuce; however, *C. nigricolor* showed an aversion to tomato and bread (this study). Literature

for tourists published in Venezuela, using the names "black lizard" and *C. lemniscatus*, indicated that *C. nigricolor* feeds on booby eggs (not confirmed in this study) and cactus flowers and fruits. These anecdotes and the observations of DDR supplement Paulissen and Walker's (1994) report that *C. nigricolor* eats some plant material, as do certain mainland populations of *C. lemniscatus* studied by Vitt et al. (1997).

Except for Grand Roque, all island populations of *C. nigricolor* in Los Roques Archipelago are herein reported for the first time (Table 1). This species should be expected through much of the archipelago on islands with suitable habitat. Insular populations also currently allocated to *C. nigricolor* are found on the Venezuelan islands Las Aves (Burt 1931), Orchila (Peters and Donoso-Barros 1970), and Blanquilla (Burt 1931; Sites et al. 1990). Margarita Island, 288 km east of Grand Roque, was listed in the range of the species by Burt (1931); however, this population was allocated to *C. lemniscatus* by Peters and Donoso-Barros (1970). With our formal taxonomic recommendation for *C. nigricolor*, since 1987 *C. lemniscatus* has been partitioned into two parthenogenetic (Cole and Dessauer 1993) and four gonochoristic species (McCrystal and Dixon 1987; Markezich et al. 1997; Sites et al. 1990; this study). *Cnemidophorus nigricolor*, as known from Los Rocques Archipelago, is the most divergent of the sexual forms related to *C. lemniscatus* in color pattern, though not in body size, reproductive characteristics, and scutellation. The transition from the striped pattern of *C. lemniscatus* to the melanistic coloration of *C. nigricolor* might represent an adaptation for island life. There are also numerous melanistic insular populations of *Cnemidophorus* in the *tigris* species group in the Gulf of California (Walker and Maslin 1969, 1981; Walker 1983); however, none of those forms undergo such marked changes from gray juvenile to black adult as *C. nigricolor*. Substrate matching might explain the basis of the gray coloration in juveniles of *C. nigricolor* that prefer open sandy areas along beach strands. Cryptic coloration might account for the advantage conferred by black coloration in adults. Photographs of melanistic individuals of *C. nigricolor* taking refuge in the dark shadows cast by low-growing vegetation suggest crypsis.

Additional data are needed to assess the relationship of *C. nigricolor* to other insular taxa (e.g., *C. arubensis* and *C. murinus*) in the Caribbean Sea (Sites et al. 1990). Also, whether all insular populations presently allocated to *C. nigricolor* outside of Los Roques Archipelago are conspecific is open to question given their geographic positions and the tendency of islands and banks in the Caribbean Sea to support endemic species of lizards (Williams 1969). Burt (1931) found considerable inter-island variation in color pattern among the specimens he examined from populations allocated to this species. Moreover, the specific status of the Margarita Island *Cnemidophorus* population is in immediate need of study because of its wide separation from Los Roques Archipelago and controversial taxonomic status (Peters and Donoso-Barros 1970).

Acknowledgments—The UCM sample of *C. nigricolor* was collected by T. P. Maslin whose past field activities continue to impact contemporary studies of whiptail lizards. We are grateful to S.-K. Wu for the privilege of examining specimens of *Cnemidophorus* in his care. We also acknowledge the significance of observations on *C. nigricolor* made by M. L. Rhoads in Los Roques Archipelago.

Sexing *Cnemidophorus* Lizards Using a Postanal Scale Character

KYLE G. ASHTON
Department of Environmental, Population, and Organismic Biology, University of Colorado, Boulder, Colorado 80309, USA

Present address: Archbold Biological Station, 123 Main Drive Venus, Florida 33960, USA
e-mail: kashton@archbold-station.org

Distinguishing between male and female individuals of a species is very important for field studies of reptiles because sex-related differences in ecology, life history and general natural history might exist. Therefore, it is essential that the sex of every individual be determined accurately. Several methods exist for differentiating between live males and females of species of reptiles. Firstly, the presence or absence of hemipenes can be determined by either inserting a probe into the cloaca or pressing on the tail of an animal to force the hemipenes to evert (Fitch 1960; Gregory 1983); however, everting the hemipenes might be difficult for some species. Secondly, sex might be determined by the presence of enlarged follicles in pregnant females or sperm in the cloaca of adult males and recently mated females (Fitch 1960). This method is obviously restricted to sexing adult, reproductive animals. Thirdly, secondary sexual characters can be used, but again this technique is limited to adult animals. Fourthly, external, postanal scale characters might be used. For instance, male phrynosomatids, and at least some other species of lizards formerly considered iguanids (*sensu lato*), possess a pair of enlarged postanal scales that can be used to identify easily the sex of a live individual in the field (see Smith 1946; Stebbins 1985). The advantage of this scale character is that it can be used to identify accurately the sex of any individual, regardless of age or reproductive status.

Pietruszka (1981) suggested that a postanal scale character, the presence or absence of a postanal plate, might be used to identify the sex of individuals of *Cnemidophorus* (see Fig. 1 of Pietruszka (1981) for a photograph of the postanal plate). Pietruszka (1981) examined specimens of 10 *Cnemidophorus* species (5 bisexual, 5 unisexual) and found that the postanal plate allowed accurate sexing of 613/614 specimens. Interestingly, this character seems to have been known for some time. While reorganizing files of correspondences housed at the University of Colorado Museum of the late T. Paul Maslin, I found a letter from T. Rodgers dated 28 November 1941 with the title "Method of sexing *Cnemidophorus tesselatus*." Rodgers writes:

> "In the males the last row of fine granules is distinctly larger than the rest, and the first two or three transverse rows of ventral tail scales are very little if any, smaller than the two or three rows posterior to them. Also, in males, the most anterior scale in the second longitudinal rows out from the mid-ventral line is conspicuously exposed or larger than the second and third scales."

Despite the description of the postanal plate by Rodgers in the

1941 letter, and formally by Pietruszka (1981), this character is not well known in the literature and, further, it is unclear whether it is useful for all *Cnemidophorus*, and possibly teiids in general.

The objective of this study was to discern further the taxonomic breath, particularly among species of *Cnemidophorus*, of this scale character, the postanal plate in males, for sex identification. The genus *Cnemidophorus* consists of approximately 50 species, a third of which are unisexual (Maslin and Secoy 1986; Wright 1993, 1994). *Cnemidophorus* lizards are a prominent member of the fauna of North and South America in terms of both abundance and diversity. Accordingly, many studies of their ecology, life history, and natural history have been performed (see Wright and Vitt 1993). However, such studies have typically only differentiated between the characteristics of adult males and females, while lumping the data for all juveniles (e.g., Echternacht 1967; Pianka 1970; Vitt and Ohmart 1977; but see Fitch 1958). Presumably the sex of live juveniles was not determined because the researchers were unable to use secondary sexual characters or reproductive traits to differentiate between males and females. In this paper I show that the scale character described by Pietruszka (1981) accurately identifies the sex of *Cnemidophorus* in general and also can be used for at least one other genus (*Ameiva*) of teiids as well.

I examined preserved males and females of 13 bisexual and three unisexual species of *Cnemidophorus* (Table 1). The species were chosen to supplement, but not repeat, the species examined by Pietruszka (1981). I also examined museum specimens of two species of *Ameiva* to test whether the postanal plate could be used for sex discrimination in another genus within the family Teiidae (Table 1). For each museum specimen I first assessed whether the postanal plate (see Fig. 1 of Pietruszka 1981) was present or absent. Next I determined the sex of the individual by making a ventral incision in the abdomen and noting whether follicles or testes were present. For some individuals, the presence or absence of hemipenes was used to determine sex because either the hemipenes were everted or they were already exposed by a prior incision in the ventral aspect of the tail.

The presence or absence of the postanal plate allowed 100% discrimination between males and females of the thirteen bisexual species of *Cnemidophorus* included in this study (Table 1). All males possessed postanal plates and all females lacked postanal plates. Further, individuals of all three unisexual species (Table 1) did not have a postanal plate, as expected because the unisexual species consist solely of females. Both species of *Ameiva* (Table 1) showed the enlarged postanal plate in all the males and none of the females examined.

Pietruszka (1981) found that the postanal plate accurately determined whether an individual *Cnemidophorus* was male or female for 613 out of 614 specimens that he examined, representing five bisexual and five unisexual species (Table 1). I found that this postanal scale character was useful in distinguishing between males and females for 332 individuals representing 13 bisexual and three unisexual species of *Cnemidophorus*, and for 40 individuals of two species of *Ameiva* (Table 1). Therefore, the postanal plate has been shown to accurately reflect the sex of an individual in roughly half of the species of *Cnemidophorus*, including members of all six species groups (Wright 1993). Accordingly, this character provides a simple method to differentiate between the sexes of live *Cnemidophorus* of all ages. Whether the postanal plate occurs in males of all species of Teiidae awaits further study.

Acknowledgments.—I thank A. de Queiroz for permission to examine museum specimens at the UCM; H. M. Smith, A. de Queiroz, H. W. Greene, and H. L. Taylor for discussion.

Courtship and Copulation in the Grand Canyon Rattlesnake, *Crotalus viridis abyssus*

ROBERT N. REED*

e-mail: reed@srel.edu

Pitvipers are useful organisms for the study of relationships between social structure and mating system (Duvall et al. 1992; Duvall et al. 1993). Courtship and copulatory behaviors have been described for a variety of free-ranging taxa (Brown 1991; Klauber 1972; MacCartney and Gregory 1988). These observations have been complemented by quantitative laboratory studies (Armstrong and Murphy 1979; Chiszar et al. 1976; Gillingham et al. 1983; Hayes 1986; Schuett and Gillingham 1988). However, behaviors exhibited in the lab might not be identical to those displayed by free-ranging individuals (Hayes et al. 1992), and additional field observations are required to establish baseline criteria for ontogeny and duration of courtship behavior within and between species.

In this paper, I report detailed observations of an incident of courtship and copulatory behavior of free-ranging Grand Canyon rattlesnakes (*Crotalus viridis abyssus*). These snakes are limited to the Grand Canyon of the Colorado River and its side canyons. Individuals approach one meter in length and have a red, salmon, or pink ground color, with slightly darker oval-shaped body blotches that fade with age (Ernst 1992; Stebbins 1985). My observations were made during a radiotelemetric study of the ecology of *C. v. abyssus* in the Little Colorado River Canyon (Coconino Co., Arizona). Although the observations reported herein are based on only two courtships and one copulation, they provide valuable data on reproductive behavior of a poorly known rattlesnake, and greatly extend the known duration of courtship in vipers as a group.

On 12 July 1993, a male *C. v. abyssus* (male #1993-13, 395 g, 765 mm SVL) was observed coiled around a radiotelemetered conspecific female (female #1992-2, 198 g, 655 mm SVL). Both snakes were coiled on packed sand under an overhanging boulder less than 3 m from the Little Colorado River. The recently shed skin of the female was found 2 m away. The pair was observed continuously from 1800 to 2300 h, at which time the male initiated forward-jerking (with simultaneous chin-rubbing) and tail-search copulatory attempts (TSCA, Gillingham 1977). The male jerked his head (averaging 2 jerks/sec) along the dorsum of the coiled female, continuously maintaining contact via the chin. Chin-rubbing was accompanied by rapid tongue-flicking. Chin-rubbing sequences (including the brief TSCA which ended each sequence) were followed by pauses (chin-rubbing sequence duration mean ± standard deviation = 29.9 ± 9.7 sec; pause duration = 67.4 ± 110.9 sec, N = 52 sequences observed). The pause length was cyclical, with longer pauses of 7–10 min. every 12 ± 2 min. Chin-rubbing sequences were more uniform in length, and each was immediately followed by TSCA, effecting cloacal apposition. During each TSCA, the male visibly strained against the cloaca of the female, often lifting the entire posterior third of her body from the substrate. Tail whipping by the female (Hayes 1986; Hayes et al. 1992; Schuett and Gillingham 1988) was observed periodically, and resulted in a pause in male courtship activity. Cloacal gaping by the female (Gillingham et al. 1983) was not observed.

Observations were stopped at 0055 h (13 July) and resumed at 0400 h, at which time both snakes had resumed resting coils. The snakes were monitored hourly until 2300 h when courtship resumed; courtship continued until 0315 h (14 July). After this, the pair was monitored every other hour. Courtship again resumed at 2110 h (14 July); however, at this time the female repeatedly withdrew her tail from the male, resulting in long and erratic tail searches by the male, as well as repeated lingual examination of the female's tail and cloaca. Activity ceased at 0030 h (15 July), then resumed from 2130 to 2300 h. Courtship did not re-commence until 1900 h the following evening (16 July).

Copulation was observed at 1950 h on 16 July. During copulation, the male actively searched the area around the pair with the anterior third of his body and tongue-flicked rapidly (1.04 ± 0.2 tongue flicks per sec over one typical five min. period). The male periodically thrusted with the hemipenis (7.6 thrusts per min. over 5 min.). Every fifth or sixth thrust was of greater magnitude and resulted in complete cloacal apposition. The pair was checked hourly, and copulation terminated at 0400 h. Following copulation, the male repeatedly pushed his cloaca onto the substrate, apparently forcing the hemipenis to revert into the tail. The male's rattle was coated with dried blood and a 25 cm^2 area under the pair was stained pink. Blood appeared to be a major component of this dilute fluid. At this time the male was captured. The hemipenis was fully inverted and no further fluid loss occurred.

Two days later (18 July), a different telemetered male (male #1992-4, 374 g, 834 mm SVL) moved 91 m from his previous position and was observed with the same female (#1992-2) at her original location. Courtship behaviors similar to those described above were initiated that evening and were observed for two nights. I terminated the field trip on 20 July, and had not observed copulation by this time.

Courtship behavior of many viperid and colubrid snakes follows a triphasic scheme of tactile-chase, tactile-alignment, and

intromission (Gillingham 1977; Schuett and Gillingham 1988). I did not observe the tactile-chase phase, which is usually of minor consequence in viperid snakes. Rather, I found both males accompanying the motionless female, and observed chin-rubbing and TSCA events shortly thereafter. The duration of courtship activities by male #1993-13 was striking in its duration (at least 92 h, including periods of quiescence between first observed TSCA and actual intromission). In contrast, free-ranging prairie rattlesnakes (*C. v. viridis*) court on average only 20 min. before successful intromission (Duvall et al. 1985), while among western diamondback rattlesnakes courtship averages nine minutes between the first TSCA and intromission (Gillingham et al. 1983). The length of this courtship raises the question of whether female Grand Canyon rattlesnakes choose mates based on relative courtship stamina. Duration of copulation (ca. 8 hours) was intermediate between 70 min. in *C. v. viridis* (Duvall et al. 1985) and 20–28 h in *C. atrox* (Gillingham et al. 1983). Additional copulations may have occurred either before observations were begun on 12 July or during times when snakes were not observed, although the latter seems unlikely considering that I made observations at two hour intervals. The sequential, non-simultaneous courtships of a single female provides circumstantial evidence for the occurrence of multiple mating in *C. v. abyssus*, as has been observed in conspecific *C.v. viridis* (Duvall and Schuett 1997) and some other viperids (Duvall and Beaupre 1998; Madsen and Shine 1994; Schuett and Gillingham 1988).

Courtship mechanics were similar to those described by Hayes (1986) for captive *C. v. oreganus*. However, I am unaware of any published account documenting the cyclical nature of pause-length in snake courtship. I speculate that longer pauses between periods of intense courtship might facilitate aerobic recovery and reduce anaerobic energy expenditure by males during female persuasion. Lastly, diurnal ambient temperatures over 40°C are common in the Grand Canyon in July. Nocturnal reproductive activity may thus reflect the infeasibility of maintaining energy-intensive behaviors at high body temperatures.

Acknowledgments.—Research was supported by the A.S.U. Graduate Research Association, the American Museum of Natural History (T.H. Roosevelt Fund) and contract BOR-1-FC-90-10490 from the Bureau of Reclamation. I thank David Duvall for loaning telemetry equipment and Pat Keegan for field assistance during 1993. The Navajo Nation provided collecting permits; research was performed under ASU Animal Protocol 92-249R. The manuscript was improved by comments from C. Guyer, D. Duvall, and G. Schuett.

Additions To Our Knowledge Of Anuran Sesamoids

JULIO MARIO HOYOS

Sesamoid bones may be a true ossification of hyaline cartilage, or may be a thickening or nodule of cartilage without ossification (Pearson and Davin 1921a). They have been found in all classes of vertebrates, but not always at the same position. Pearson and Davin (1921a, b) described sesamoid bones in all vertebrate classes, introducing a new nomenclature for some of them. Haines (1942, 1969) described these elements for lizards, and Nussbaum (1982) for frog families.

Alexander and Dimery (1985) studied sesamoid bones of mammals and their relationship with the mechanics of joints. Maybe the best work about heterotopic bones in frogs was done by Nussbaum (1982). He discovered that these elements have an important role for resolving phylogenetic hypotheses about relation-

ships of families and subfamilies in frogs, even so he asserted that "There are few and scattered reports of sesamoid elements in frogs" (p. 312). He identified three tarsal sesamoids (which he called heterotopic skeletal elements): cartilago plantaris, cartilago sesamoides, and os sesamoides tarsale—from Ranidae, Pipidae, and Sooglossidae. The first one is found on the plantar surface of the foot between the fibulare and the fourth metatarsal; the second one slides over the proximal head of the tibiale, and the last one is continuous with the proximal and distal portions of the aponeurosis plantaris near the distal end of the tibiale, and being always bigger than the cartilago sesamoides.

In the same way, Olson (2000) studied heterotopic elements (which she called "extraskeletal bones") but only in one species (*Hymenochirus boettgeri*). However, she provided a detailed description of some of the elements previously described by Parsons and Davin (1921a, b) and by Nussbaum (1982), and incorporated new descriptions and names to heterotopic elements.

I examined some sesamoid bones of the hands and feet, which have not been studied in a systematic way, and are often neglected in species descriptions and anatomical studies. It is important to consider that we should pay more attention to these elements for resolving frog relationships (e.g., Laurent 1940, 1961). In ranoid species, some reports as those by Laurent (1942, 1961) have shown the existence of subarticular sesamoids found below the carpus in Arthroleptinae (*Arthroleptis wahlbergi*, Ranidae); however, Laurent (1961) stated that this bone may be present in the other Arthroleptinae although fused with the second, fourth, and fifth carpals. Thus, he found in Hyperoliidae a sesamoid bone behind the tibio-tarsal articulation, and subarticular sesamoids in *Dendrobates trivitatus* and in *Atelopus varius*. In this paper I report heterotopic elements not previously mentioned in the literature for these species of ranids; likewise, I report hand and foot sesamoid bones that have not been mentioned in the majority of papers in some ranoid (*sensu* Dubois 1992) and leptodactylid species, and instances of the sesamoids mentioned by Nussbaum (1982) in species not reported by him.

I examined one to ten specimens in each of 53 species of the family Ranidae (*sensu* Dubois 1992); two specimens and one species of the family Mantellidae (*sensu* Dubois 1992); two specimens and one species of the family Phrynobatrachidae (*sensu* Dubois 1992); four specimens and two species of the family Arthroleptidae; five specimens and three species of the family Microhylidae; two specimens and one species of the family Hyperoliidae, and two specimens and one species of the family Leptodactylidae (see Appendix 1). All specimens were cleared and stained following Dingerkus and Uhler's (1977) clearing and double-staining method.

The cartilago sesamoides (Fig. 1) occurs in the following taxa that lack the os sesamoides tarsale: Arthroleptidae: *Arthroleptis poecilonotus*, *Astylosternus occidentalis*; Hyperoliidae: *Leptopelis christyi*; Microhylidae: *Breviceps mossambicus*; Leptodactylidae: *Eleutherodactylus martinicensis*; Ranidae: *Amolops monticola*, *Conraua crassipes*, *Conraua alleni*, *Euphlyctis cyanophlyctis*, *Hoplobatrachus occipitalis*, *Hoplobatrachus rugulosus*, *Ingerana tenasserimensis*, *Limnonectes blythii*, *Limnonectes kuhlii*, *Limnonectes pileatus*, *Mantella madagascariensis*, *Nanorana parkeri*, *Occidozyga lima*, *Paa blanfordii*, *Paa vicina*, *Phrynobatrachus accraensis*, *Phrynoglossus laevis*, *Phrynoglossus magnapustulosus*, *Phrynoglossus martensii*, *Ptychadena superciliaris*, *Rana albolabris*, *Rana chapaensis*, *Rana clamitans*, *Rana erythraea*, *Rana esculenta*, *Rana lessonae*, *Rana perezi*, *Rana taipehensis*, *Rhacophorus leucomystax*, *Rhacophorus nigropalmatus*, *Taylorana hascheana*, and *Tomopterna breviceps*.

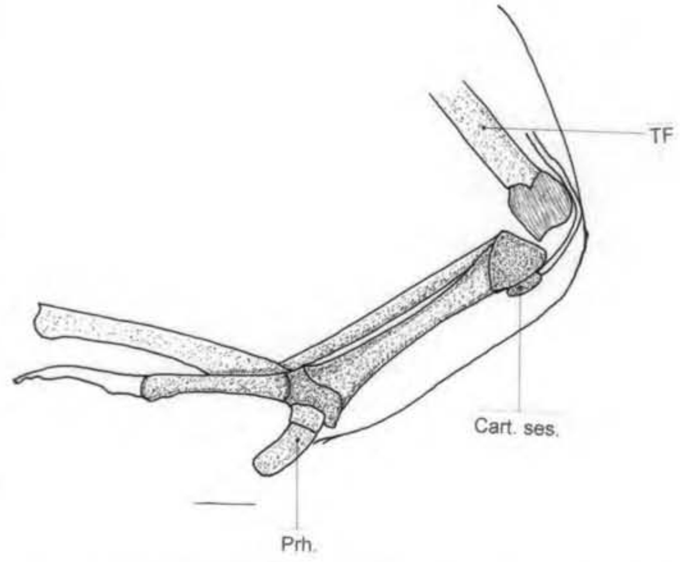

FIG. 1. Ventral aspect of the foot in *Occidozyga lima* CAS 195994. Cart. ses. = Cartilago sesamoides; Prh. = prehallux; TF = Tibiofibula. Scale = 1 mm.

Two of the three heterotopic elements described by Nussbaum (1982), the os sesamoides tarsale and the cartilago sesamoides, occur only in some species of the family Ranidae examined (Fig. 2): *Limnonectes limnocharis*, *Ptychadena tourneri*, *Rana arvalis*, *Rana dalmatina*, *Rana graeca*, *Rana galamensis*, *Rana iberica*, *Rana nigrovittata*, and *Rana temporaria*. Olson (2000), stated that the cartilago sesamoides is unique (an autopomorphy) to *Hymenochirus*; this is an odd observation, because Nussbaum (1982) found this element in many species that he examined.

I found sesamoid bones at the forelimb and hind limb in *Phrynoglossus martensii* (Fig. 3a): in the hind limb at the distal end of the metacarpals, and between the distal end of the first phalange and the proximal one of the second phalanx. In the same

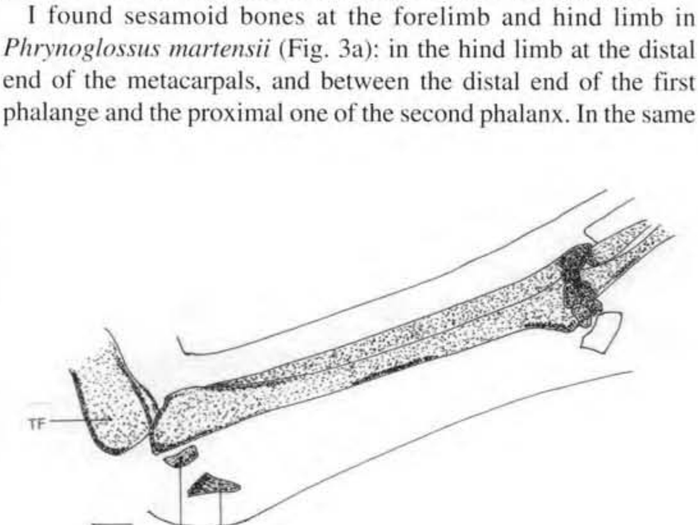

FIG. 2. Medial aspect of the left foot proximal elements in *Rana nigrovittata*. MNHN 1997. 4045. Cart. ses. = Cartilago sesamoides; Ses. tars. = Os sesamoides tarsale; TF = tibiofibula. Scale = 1 mm.

manner, in this same species, I found some sesamoid elements at the distal end of the radioulna, and at proximal one of the first metacarpal (presumably the "radial sesamoids" of Olson [2000]): *Hoplobatrachus occipitalis* (phalanges), *Ptychadena tourneri* (phalanges and metacarpal zone), *Ptychadena pujoli* (phalanges and metacarpal region), *Limnonectes limnocharis* (dorsal and ventral level of phalanges; distal level of the humerus), *Ingerana tenasserimensis* (phalanges and the distal end of the radio-ulna), and *Rana arvalis* (between tha radiale and ulnare).

Subarticular elements at the level of feet phalanges (Fig. 3b) exist in *Phrynoglossus martensii*, *Ptychadena tourneri*, *Limnonectes limnocharis* (double sesamoids in phalanges), *Astylosternus occidentalis* (at the distal end of the ventral region of tarsals, but this does not correspond to the cartilago plantares), *Ingerana tenasserimensis*, and *Mantella madagascariensis*. These sesamoid elements were not noted by Nussbaum (1982) or Olson (2000).

Pearson and Davin (1921b) reported a sesamoid bone ("mesial posterior lunula") in *Leptodactylus pentadactylus* and *Docidophryne gigantea*. This is located ventrally at the popliteal (back of the knee) region (medial region between the femur and the tibiofibula). Because only two species were included in the Pearson and Davin (1921b) study and the "mesial posterior lunula" was not figured, I am unable to determine if this is the same structure I describe in this paper (Fig. 4), referring specifically to the sesamoid in the popliteal region.

Therefore, I believe that the sesamoid in the popliteal region is a mesial fabella, in the same manner that Hoyos (1999) and Olson (2000) claimed; this element is present in the following taxa examined: *Anodonthyla boulengeri*, *Arthroleptis poecilonotus*, *Aubria subsigillata*, *Boophis brachychir*, *Chiromantis rufescens*, *Conraua alleni*, *Kaloula poulchra*, *Leptopelis christyi*, *Nanorana parkeri*, *Occidozyga lima*, *Paa blanfordii*, *Platymantis vitiensis*, *Ptychadena floweri*, *Ptychadena mascareniensis*, *Ptychadena pujoli*, *Ptychadena superciliaris*, *Pyxicephalus adspersus*, *Rana angolensis*, *Rana clamitans*, *Rana nigrovittata*, *Rana lessonae*, *Rana perezi*, *Rana pipiens*, *Rana temporaria*, *Rhacophorus leucomystax*, *Tomopterna breviceps*, and *Tomopterna marmorata*. Owing to its occurrence in many taxa, it is now clear that this element is not an autapomorphy for *Hymenochirus* as proposed by Olson (2000).

Using the nomenclature applied by Pearson and Davin (1921a, b), I believe that this last sesamoid bone is a mesial fabella because it is found in the tendons of the *musculus gastrocnemius*. This element is present also in mammals (Budras et al. 1989; Pearson and Davin 1921a), but as lateral and mesial fabellae. The mesial fabella might be confused with a mesial cyamella, a term introduced also by Pearson and Davin (1921a) for the sesamoid that is found in the tendon of the *M. popliteus*, a muscle placed near from the *M. gastrocnemius*, not present in frogs. Because this bone was not reported by Nussbaum (1982), his discussion about morphology and phylogeny of frogs was based upon the cartilago sesamoides and the os sesamoides tarsale. He noted the fact that the cartilago sesamoides occurs in many species of frogs that lack the os sesamoides tarsale, such as I found in a number of species, emphasizing the widespread occurrence of the cartilago sesamoides among frogs. At the same time, Nussbaum's hypothesis that the os sesamoides tarsale is of much more limited occurrence in frogs

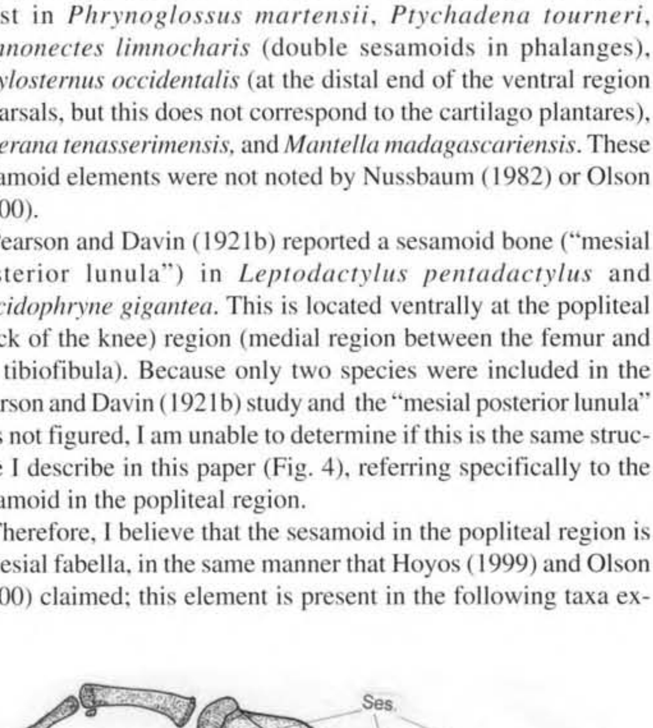

FIG. 3. a. Dorsal aspect of the right hand in *Phrynoglossus martensi*. MNHN 1987.5376. Ses. = ossa sesamoidea; Prp. = prepollex b. Ventral aspect of he right hand in *Phrynoglossus magnapustulosus* .MNHN 1997.5376. Ses. = Os sesamoides. Scale = 1 mm.

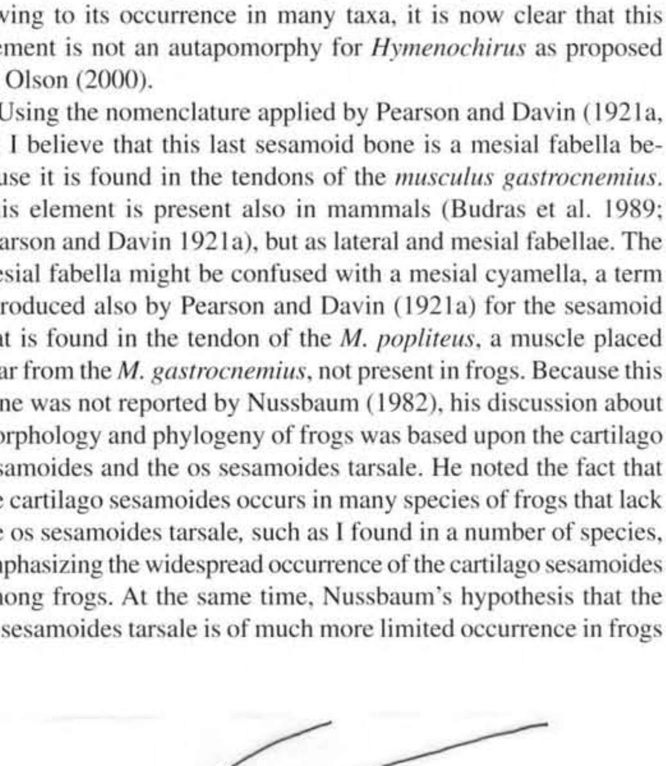

FIG. 4. Ventral aspect of the right hindlimb in *Rhacophorus nigropalmatus* showing the mesial fabella between the femur and tibiofibula. MNHN 1997.4094. TF = tibiofibula. Fe = femur. Scale = 1 mm.

was verified by my results. It is also important to emphasize that the os sesamoides tarsale never appeared without the presence of the cartilago sesamoides, whereas the later was often found without the former.

Nussbaum (1982) reported the os sesamoides tarsale from only three groups of frogs—*Pipa*, Sooglossidae, and Phrynobatrachinae—but I found this element in additional species not examined by Nussbaum. Therefore, the hypotheses of phylogenetic relationships proposed by Nussbaum should be examined carefully in light of this additional information. If the os sesamoides tarsale is present in fewer taxa than compared with the cartilago sesamoides, the former could be more useful in frog systematics, but the contrary, that the cartilago sesamoides is present in fewer taxa than the os sesamoides tarsale, is also true. In following Nussbaum's rationale, we could say that the presence of the os sesamoides tarsale is derived and its absence is primitive. But I think we will need an actual cladistic analysis in using outgroups to corroborate this assessment.

As I did not find the os tibialis anticus, we could support the proposal by Olson (2000) that considers this element as an autapomorphy for *Hymenochirus*. Likewise, I did not find the posterior lunula examined by Olson (2000), therefore I think we need to consider that this character is an autapomorphy for *Hymenochirus*, as this was stated by Olson (2000). It is important to stand out that although papers by Laurent et al. (1989–1990), Fabrezi (1992, 1996, 2001), Fabrezzi et al. (1996), and Fabrezzi et al. (2001) mention phalanx and carpal elements, they did not treat sesamoid elements in an explicit way.

It is clear that, opposed to Olson (2000), heterotopic elements are common in amphibians, bearing in mind that anurans comprise majority of amphibians. However, we need to investigate more about these sesamoid bones, namely the os sesamoides tarsale and the mesial fabella, to discover their taxonomic and phylogenetic importance in frog systematics.

Acknowledgments.—I thank Alain Dubois (Muséum National d'Histoire Naturelle, Paris MNHN) for the loan of specimens and encouragement; Robert Drewes from the California Academy of Sciences (CAS) for the loan of specimens, and Manuel Ruiz (Pontificia Universidad Javeriana, Bogotá) for a previous review of the manuscript and to John Mario González for helping in improving the English text.

The benefits of pest control attributed to amphibians are usually based on anecdotes rather than on experimental field tests (Matheson and Hinman 1929; Minton 1972). One study testing the effect of adult European frogs on mosquito density established that the frogs ate mosquitoes, but had no regulatory effect (Blum et al. 1997). In a North American study on adult eastern newts (*Notophthalmus viridescens*) the authors (Matheson and Hinman 1929) concluded that newts are efficient at reducing mosquito populations. However, the conclusions were based on qualitative observations at just three wetlands and upon the predatory behavior of three newts in a small glass jar. The hypothesis that amphibians can reduce mosquito population density has not been tested quantitatively on aquatic salamanders in a natural setting or with adequate replication.

Pond-breeding salamander larvae of the genus *Ambystoma* are opportunistic carnivores that often occur at high densities in temporary ponds (Brodman 1995; Peterson et al. 1992; Van Buskirk and Smith 1991). Because larval mosquitoes are confined to the aquatic habitat, opportunities to escape predation are more limited compared to flying adults. These factors suggest that the larvae of pond-breeding salamanders might be better candidates than adults for reducing larval mosquito density. The diet of the larvae of North American pond-breeding salamanders generally consists of zooplankton, aquatic insects, benthic crustaceans, and occasionally amphibian larvae (Freda 1983; Gehlbach 1965; Holomuzki 1989; Morin 1981; Nyman 1991; Sever and Dineen 1978; Smith and Petranka 1987). Pest dipteran species including mosquito larvae are often components of the diet (Hutcherson et al. 1989; Sever and Dineen 1978; Smith and Petranka 1987). Several studies have had mixed results, indicating that some but not all invertebrate prey taxa are reduced in population density or biomass because of predation by certain species of salamander larvae (Harris 1995; Holomuzki 1989; Holomuzki et al. 1994; Petranka 1989). Whereas marbled salamander larvae (*A. opacum*) do not affect zooplankton biomass, tiger salamander larvae (*A. tigrinum*) can reduce zooplankton biomass and densities of microcrustaceans and dipterans (Holomuzki 1989; Holomuzki et al. 1994). Spotted salamander (*A. maculatum*) larvae reduce densities of benthic crustaceans but not microcrustaceans (Harris 1995). There have been no studies on the effect of coexisting salamander species representing two size classes of larvae on aquatic invertebrates nor on the effect of salamander larvae on mosquito populations.

The purpose of this paper is to couple natural observations, using a set of wetlands that either have or lack salamander populations, with an experiment using mesocosms to test the hypotheses that: 1) presence or absence of salamander larvae influences the aquatic invertebrate community; 2) two species of coexisting salamander larvae of differing size classes have an interactive effect on the aquatic invertebrate community; and 3) salamander larvae can reduce mosquito populations.

For the natural observations we surveyed 100 wetlands in Jasper, Pulaski, and White counties in northwest Indiana for the presence and relative abundance of amphibians from 1994 to 1998. The primary methods employed in this survey were assessment of frog calling intensity and directed sampling, which included searches under cover objects adjacent to wetlands and sampling wetlands with aquatic seine, dipnet and minnow traps. Relative abundance of each species was determined by the number caught in directed sampling per person hour of effort and by applying a breeding index scale from 0 to 5 (see Karns 1986). Voucher specimens were taken for new site and county records and deposited in the Saint Joseph's College repository (Brodman 1999).

To correlate amphibian abundance with habitat characteristics, physical parameters of each wetland were determined on site and with the aid of National Wetland Inventory maps and aerial photographs (Smallwood and Osterholz 1990). Parameters recorded include the area of the wetland, estimated percentage of wetland covered by emergent vegetation during spring, and the presence of wood stands (> 1 ha) within 200 m of wetland. We $\log_{10}$-transformed wetland size before statistical analysis. Hydroperiod was determined by using National Wetland Inventory maps, and modified based on five years of observation. Each wetland was given values reflecting hydroperiod as follows: saturated (value = 0.1), temporary (value = 0.3), seasonally flooded (value = 0.5), semipermanently flooded (value = 0.7), intermittently exposed (value = 0.9), and permanently flooded (value = 1.0). These values approximate the probability of the wetland holding water through-

out the summer.

Water samples were collected from three random locations in each wetland by lowering a 1 L container from surface to bottom such that the water sample would represent the entire water column. Water samples were analyzed for chemical composition using LaMotte water testing kits (Renn 1970). Dissolved oxygen, carbon dioxide and pH were determined on site. Water samples were brought to the lab to test for concentrations of phosphate, silica, ammonia, nitrate, sulfate, hardness, and turbidity.

TABLE 1. Comparison of mean (± standard error) wetland characteristics between wetlands with and without salamanders. *P*-values are from one-tailed Mann-Whitney *U* tests.

Wetland Characteristic	With Salamanders	Without Salamanders	*p*
Anuran species richness	3.0 ± 0.6	3.7 ± 0.7	0.24
Abundance (calling intensity)	7.3 ± 1.8	10.2 ± 2.0	0.15
Wetland area (log m^2)	7.3 ± 0.9	7.5 ± 0.4	0.43
Percent emergent vegetation cover	43.2 ±10.0	48.3 ± 7.5	0.34
Percent with woods within 200 m	66 ± 14	83 ± 11	0.18
Hydroperiod	0.42 ± 0.15	0.33 ± 0.14	0.34
pH	6.9 ± 0.2	6.9 ± 0.2	0.82
Dissolved Oxygen ppm	10.2 ± 1.4	8.8 ± 0.9	0.20
Carbon dioxide ppm	41.3 ± 10.5	50.8 ± 7.8	0.24
Phosphate ppm	0.74 ±0.39	0.34 ± 0.08	0.17
Silica ppm	5.0 ± 1.2	6.5 ± 0.9	0.17
Ammonia ppm	0.30 ± 0.07	0.20 ± 0.06	0.11
Nitrate ppm	125 ± 26	92 ± 16	0.15
Sulfate ppm	31 ± 5	30 ± 4	0.41
Hardness ppm	125 ± 33	111 ± 16	0.36
Turbidity jtu	46 ± 12	64 ± 9	0.12

From our pool of 100 wetlands, we selected 12 sites that had salamander larvae present and matched them with 12 sites that lacked salamanders. Each set of 12 sites included four temporary or seasonally flooded wetlands that hold water from late winter through spring, four semi-permanently flooded wetlands that held water from late winter through three of the five summers, and four intermittently exposed or permanent wetlands that held water throughout all five years. Six pairs of sites were located at state nature preserves, two pairs of sites were located on Saint Joseph's College property, and the remaining four pairs of sites were wetlands located on rural private properties. The salamander sites included four sites with tiger salamanders, two sites with blue-spotted salamanders (*A. laterale*), and six sites with two or three species that included combinations of tiger salamanders, blue-spotted salamanders, small-mouth salamanders (*A. texanum*), eastern newts, and lesser sirens (*Siren intermedia*). Salamander and salamander-free sites were matched based on having similar locations, frog faunas, physical parameters and water chemistry. All 24 sites were fish-free. We used the non-parametric one-tailed Mann-Whitney *U* test of the null hypothesis that there are no differences among the wetland characteristics between sites with and without salamander larvae. The chosen wetland sites with salamander larvae present did not significantly differ from our salamander-free sites (Table 1).

We sampled each of these 24 wetlands for aquatic invertebrates on four dates (early April, late April, early May, and late May). Three 1 L water samples were collected on each date from each wetland by lowering a 1 L container (with a 6 cm diam circular opening) from surface to bottom such that the water sample would represent the entire water column. Water samples were brought back to the lab and aquatic invertebrates were identified and counted under dissecting microscopes. The site-specific mean density for each taxon was determined for all four collecting dates. ANOVA was used as an exploratory analysis to test for differences in invertebrate densities between sites with and without salamander larvae.

Mesocosms were established in a common garden experiment to test for the effect of tiger salamander (*Ambystoma tigrinum*) and blue-spotted salamander (*A. laterale*) larvae on the aquatic invertebrate community. Tiger salamanders and blue-spotted salamanders were chosen because they are the two most abundant salamander species in the study area (Brodman and Kilmurry 1998) and represent two size-classes of wetland predator. The SVL of 30 d old tiger salamander larvae are on average 33% longer than coexisting blue-spotted salamander larvae (Jaskula and Brodman 2000).

Uniform mesocosms were created in 85 L (0.15 m^2) plastic tubs with 70 L of pond water (depth 47 cm) and 10 cm leaf litter covering the tub bottom. Colonies of algae, zooplankton, benthic crustaceans, and aquatic insects were established in each mesocosm Mesocosms were placed outdoors within an oak forest and left open to the air to allow colonization of breeding insects. Forty northern leopard frog (*Rana pipiens*) eggs were added to each mesocosm to serve as an alternate prey for the salamander larvae. Salamander eggs were collected from breeding sites and hatched in the lab. Each mesocosm was supplemented with 400 ml of pond water containing zooplankton 30 d and 60 d after the experiment began.

TABLE 2. Comparison of mean aquatic invertebrate densities (number per L of water) in wetlands with and without salamander larvae. Aquatic invertebrate taxa categories are Ostracods (Ostr), Cladocerans (Clad), Mosquitoes (Mosq), Copepods (Cope), all other taxa (Other) and Total. *P*-values are from exploratory one-way ANOVA.

	Ostr	Clad	Mosq	Cope	Other	Total
Without salamanders	71.4	56.2	28.8	13.7	6.1	176.2
With salamanders	14.4	50.2	0.7	11.8	5.6	107.5
p-values	0.01	0.27	0.003	0.36	0.43	0.05

In a 2 x 2 factorial design, the control and treatments were randomly assigned to mesocosms within six blocks. Each block had a control mesocosm with no salamander larvae, a treatment with four tiger salamander hatchlings added, a treatment with six blue-spotted salamander hatchlings added and a treatment with two tiger salamander and three blue-spotted salamander hatchlings added. The initial densities of 27–40 salamander larvae/m^2 in each mesocosm are within the range of natural densities for *Ambystoma* hatchlings (Brodman 1995; Cortwright 1988; Stangel 1988; Van Buskirk and Smith 1991). The asymmetry in the number of each species of salamander used reflects the size difference between the large tiger salamander larvae and the small blue-spotted salamander larvae.

TABLE 3. Results from common garden experiment: Leopard frog tadpoles (number surviving) and aquatic invertebrate densities (number per L of water) in the presence and absence of tiger salamander and blue-spotted salamander. *P*-values are from 2 x 2 factorial ANOVA testing for the effect of salamander presence and interaction effect of the two species on aquatic community.

	Tadpoles	Zooplankton	Mosquitoes	Other diptera
Control	29.4	45.2	9.0	2.0
Blue-spotted	4.3	4.8	0.8	0.3
Tiger	0.2	0.8	0.8	0.0
Tiger+blue-spotted	0.5	1.0	0.5	0.0
p-values (vs. control)				
Salamanders present	< 0.0001	< 0.00001	< 0.0002	< 0.01
Interaction	< 0.04	< 0.0003	1.0	0.36

Water samples were collected from each mesocosm after 90 d when some of the salamander larvae were beginning to metamorphose. One-L samples were brought to the lab where aquatic invertebrates were identified and counted under dissecting microscopes. Surviving leopard frog tadpoles were also counted in each mesocosm. A 2 x 2 factorial ANOVA was used to test the effect of salamander presence on leopard frog tadpole and aquatic invertebrate densities.

After the completion of the common garden experiment, a small aquarium dipnet was used to transfer mosquito larvae and zooplankton from control to treatment mesocosms. Predatory acts by salamander larvae were observed for several days.

Cladocerans, ostracods, mosquito larvae, and copepods were the four most abundant taxa of aquatic invertebrates, making up 94–97% of the invertebrates. Wetlands with salamander larvae had significantly lower densities of mosquito larvae, ostracods, and the total number of aquatic invertebrates than salamander-free wetlands (Table 2). Mosquito larvae densities were 98% lower in wetlands with salamander larvae compared to salamander-free wetlands. There were no significant differences in the densities of cladocerans, copepods, and all of the rarer taxa.

Mesocosms with tiger salamander or blue-spotted salamander larvae had significantly lower densities of leopard frog tadpoles, zooplankton (cladocerans, ostracods, and copepods), mosquito, and other dipteran larvae after 90 d than salamander- free mesocosms (Table 3). Densities of mosquito larvae in mesocosms with salamander larvae were 91–94% lower than controls. Treatments with tiger salamanders had significantly lower densities of leopard frog tadpoles and zooplankton than treatments with blue-spotted salamanders, but there was no difference in dipteran densities with respect to salamander species (Table 3). There were significant interactive effects of the salamander species on tadpole and zooplankton densities, but not on dipteran densities.

After completion of the common garden experiment, salamander larvae were observed to prey upon mosquito larvae and zooplankton that had been transferred from the control mesocosm. Both tiger salamander and blue-spotted salamander larvae ate most of the mosquito larvae within a few days.

The field results were consistent with experimental results from mesocosms. Wetlands and mesocosms with salamander larvae had lower densities of aquatic invertebrates, including an order of magnitude reduction of mosquito densities compared to salamander-free wetlands and mesocosms. These are the first data that demonstrate that amphibian populations can greatly reduce larval mosquito densities.

Predation by aquatic salamanders has a large and often keystone effect on wetland community structure (Fauth and Resetarits 1991; Morin 1981). Studies have indicated that aquatic salamanders can reduce densities of invertebrates (Harris 1995; Holomuzki 1989; Holomuzki et al. 1994) and tadpoles (Morin 1981; Van Buskirk and Smith 1991). We provide evidence that tiger and blue-spotted salamander larvae can reduce aquatic invertebrate and leopard frog tadpole densities.

We suggest that the larvae of pond-breeding salamanders have the potential for pest control of mosquitoes and other biting flies that use temporary wetlands. Because insecticides have been implicated as a possible cause of amphibian malformations (Fort et al. 1999; La Clair et al. 1998; Madden 1993; Ouellet et al. 1997) as well as other sub-lethal and lethal effects (Boone and Bridges 1999; Boone and Semlitsch 2001; Zaga et al. 1998), an undesirable side-effect of insecticide use might be the decline of a natural predator capable of controlling mosquito populations.

TECHNIQUES

Herpetological Review, 2003, 34(2), 119–121.

Evaluation of Fluorescent Marking Techniques Using Cannibalistic Salamander Larvae

ERIK HARVEY
Department of Biology, Arizona State University
P.O. Box 871501, Tempe, Arizona 85287-1501, USA
e-mail: eharvey@asu.edu

Many marking techniques are available for identifying amphibians in ecological studies, including toe clipping, tattooing, freeze branding, staining, transponder implants, and injected fluorescents (reviewed in Donnelly et al. 1994; Brown 1997). The main concerns associated with any marking technique are retention of marks over time (e.g., Davis and Ovaska 2001), direct effects on mortality or morbidity (Clarke 1972; Daugherty 1976; Jehle and Hödl 1998), and more indirect effects on predation risk or growth (Travis 1981; Turner 1960). Subcutaneous injection of fluorescent gels is gaining wide use because, in comparison to other techniques, it is relatively inexpensive, long lasting, and noninvasive (Nishikawa and Service 1988; Seale and Boraas 1974; Wolley 1973). I conducted laboratory experiments to evaluate two injection-based alternatives for marking aquatic salamander larvae: organic dye (Seale and Borass 1974) and Visual Implant Elastomer (VIE; Anholt et al. 1998).

These experiments were motivated by two specific concerns. Firstly, Anholt et al. (1998) reported successful use of VIE for marking ranid tadpoles, but that use of organic dyes was not successful. I was interested in determining whether this was also the case for another taxon, namely aquatic salamander larvae. Secondly, there are concerns that fluorescent gel marking might affect predation risk, either by increasing visibility of marked individuals or the viscosity of marks near tail musculature hampering escape responses (Anholt et al. 1998; Davis and Ovaska 2001; Wolley 1973). In cannibalistic species, high interaction rates among predators and prey might exacerbate such effects. Aggressive encounters among Arizona tiger salamander (*Ambystoma tigrinum nebulosum*) larvae are frequent and often result in loss of extremities or cannibalism (Brunkow and Collins 1998; Collins and Cheek 1983). Marked individuals might then effectively be carrying fluo-

rescent bulls-eyes on their backs that draw the attention of cannibalistic larvae hunting for conspecifics, especially in turbid habitats. The relatively high risk of predation and injury in these largely visual predators makes *A. t. nebulosum* ideal for evaluating fluorescent marking in cannibalistic salamanders, and comparing results to previous studies conducted with anurans.

Experimental *A. t. nebulosum* larvae came from a single lab-bred clutch. Embryos hatched in shallow pans, were placed in a 180-liter aquarium, and fed brine shrimp (*Artemia* sp.) nauplii until 5 July 2000 when mean snout–vent length (SVL) was approximately 20 mm. Ten larvae each were then randomly assigned to 24 35-liter aquaria, and aquaria were randomly assigned one of three treatments in a randomized block design: 1) larvae marked with VIE (N = 6 aquaria); 2) larvae marked with organic dye-based gel (N = 6 aquaria); and 3) unmarked control larvae (N = 12 aquaria). The larger number of control replicates was required to accommodate the second experiment described below. Experimental larvae were marked using a 25 G needle to inject a stripe of gel ca. 2 mm long into the dorsal fin above the tail musculature. The organic dye was mixed to match the color of red VIE such that they were visually indistinguishable. Each tank was given daily aliquots of brine shrimp nauplii (the amount hatching from 1.5 g of cysts), and partial water changes were performed weekly. After 30 days, the numbers of larvae that survived and retained marks were recorded, and larvae were examined for signs of injury that may have concealed marks (i.e., damage to the tail fin at the marking site).

A second experiment was performed to determine whether marked larvae were more likely to be cannibalized than unmarked larvae. Individuals from the previous experiment were used because marked larvae had retained marks for one month, reducing the likelihood that lost marks would confound results. Cannibalism in *A. t. nebulosum* also only occurs when there is an approximately 2:1 size ratio between predator and prey (Ziemba et al. 2000). On 10 August 2000, when larvae ranged in size from about 25 to 50 mm SVL, the remaining 48 marked larvae from the organic dye replicates were placed in a 180-liter aquarium with 48 haphazardly selected unmarked control larvae. Likewise, 48 haphazardly selected marked larvae from the VIE replicates were placed in a separate 180-liter aquarium with 48 control larvae. Both tanks received equal daily aliquots of brine shrimp nauplii. After 60 days, surviving marked and unmarked larvae were counted and inspected for damage.

Survivorship in the first experiment was uniformly high (9 or 10 larvae survived in all replicates), and not different among treatment levels (Kruskal-Wallis H = 1.42, p = 0.492). Retention of marks was higher in the VIE treatment (mean ± SEM = 100% ± 0%) than the organic dye treatment (84.3% ± 2.27%). All surviving larvae marked with VIE retained their marks, while at least one larva in each organic dye replicate lost its mark (Mann-Whitney U = 0.0, p = 0.002). Marked larvae in the second experiment were not more likely to be cannibalized than unmarked larvae for either the VIE or organic dye treatment (Table 1; Mantel-Haenszel c^2 = 0.0219, p = 0.882). Although some larvae died for reasons other than cannibalism (presumably from complications associated with attempted cannibalism; N = 12 of 118 deaths across both treatments), outright cannibalism was the main source of mortality (N = 106 of 118 deaths). Because there were relatively few non-cannibalistic deaths and these were likely a consequence of cannibalism attempts, all deaths were included in the analysis. All larvae incurred at least some damage to limbs, gills, or tail tips from intraspecific encounters, but injuries occurred well away from the marking site such that identifying marked versus unmarked individuals was unambiguous.

Table 1. Results of cannibalism experiment where equal numbers of marked and unmarked larvae were placed together to assess the effect of marking on the incidence of deaths from intraspecific predation and aggression.

	V.I.E.			Organic Dye		
	Lived	Died	Sum	Lived	Died	Sum
Marked	22	26	48	15	33	48
Not marked	19	29	48	18	30	48
Sum	41	55	96	33	63	96

Neither gel-based marking technique reduced survivorship of larvae relative to unmarked larvae. Similarly, neither marking technique affected cannibalism rate. However, the cannibalism experiment was conducted in a well-lit laboratory in clear water, and colored marks may increase visibility of larvae to potential predators in turbid waters of natural habitats. Salamander larvae retained VIE marks better than organic dye, but two additional considerations might offset this advantage. Firstly, VIE is more expensive than the organic dye gel. A 15 cc kit of VIE (enough to mark about 1500 larvae) costs US $190 versus approximately US $19 for a comparable amount of organic dye gel. Secondly, VIE must be prepared immediately prior to use. Although keeping VIE refrigerated will slow the hardening process, it must be used within a few days of mixing ingredients (Northwest Marine Technology, Inc. 1999). Organic dye gel seems to last indefinitely (pers. obs.), allowing one to mix large batches that can be used for years. If maximum retention of marks is a priority, however, the extra cost and effort associated with the VIE system might be worthwhile.

Acknowledgments.—My thanks to P. Benbrook and J. Roth for assistance in the laboratory, and to J. Collins and C. Secor for reviewing early drafts of the manuscript. Experiments were conducted under Arizona State University I.A.C.U.C. protocol #99-510R.

A Simple Model for Estimating the Age of Morelet's Crocodile Embryos

Crocodile research and management often requires information on the timing of various aspects of reproduction (Magnusson and Taylor 1980). The ability to determine accurately embryo age allows estimation of oviposition dates, monitoring embryo mortality within nests, and prediction of hatching peaks (Hall 1985; Magnusson and Taylor 1980; Webb et al. 1983a, b). Crocodilian embryos have been aged on the basis of ontogenetic stages (Ferguson 1987; Magnusson and Taylor 1980) and the extent of opaque egg banding (Ferguson and Joanen 1983; Webb et al. 1983a, b), but these methods are time consuming, highly subjective, and difficult for non-embryologists to apply in the field (Deeming and Ferguson 1990; Hall 1985). Instead, Webb et al. (1983a, b) and Hall (1985) recommend the development of species-specific growth models that relate selected morphometric measurements to embryo age. Such models are available for *Crocodylus johnstoni* (Webb et al. 1983a), *C. novaeguineae* (Hall 1985), *C. palustris* (Hall 1985), and *C. porosus* (Hall 1985; Webb et al. 1983b), and in this paper we provide a model for Morelet's crocodile (*C. moreletii*), a little-studied species inhabiting the Caribbean and Atlantic lowlands from northern Mexico south to Guatemala and southern Belize (Groombridge 1987; Platt et al. 1999).

This study was conducted from June through September 1996 at Gold Button Lagoon (17°50' N; 88°45' W), a 142-ha man-made impoundment in Orange Walk District, Belize inhabited by an estimated 175 non-hatchling crocodiles (Platt 1996). At the onset of the nesting season (mid- to late June), we inspected potential nest sites every two days and determined the oviposition date of each clutch to within 48 h. Beginning two to three weeks post-laying, a single viable egg was randomly collected from every nest each week. Linear measurements of eggs and embryos were obtained with dial calipers (± 0.1 mm). Egg length (EL) was measured and the embryo extracted after euthanization by chilling at approximately 10°C for one hour (Platt et al. 2000). Previous studies (Deeming and Ferguson 1990; Hall 1985) have identified dorsal cranial length (DCL: measured from the anterior tip of the snout to the median posterior edge of the supraoccipital) as the best morphological attribute for predicting embryonic age in crocodilians. Unlike other attributes, DCL exhibits isometric growth with respect to embryo age and can be easily measured (Hall 1985). On young embryos lacking cranial ossification, DCL was measured from the anterior tip of the snout to the flexion of the cranial region (see Fig. 1 of Hall 1985), and care was taken to ensure calipers did not indent soft tissue. Embryos were preserved in formalin and later deposited in the Campbell Museum, Clemson University, Clemson, South Carolina, USA. Weekly egg collection continued until clutches were lost to predation or flooding, or hatched. In most cases, the date of hatching was unknown and thus incubation period could not be precisely determined.

Thirty-two embryos ranging from 17 to 73 days old were collected from seven *C. moreletii* nests between 6 July and 14 September. There was a significant positive relationship between embryo age and DCL, and DCL explained most of the variation in embryo age ($r^2 = 0.91$; $P < 0.001$; Fig. 1). The average difference between predicted embryo age and actual age was 4.0 days (range

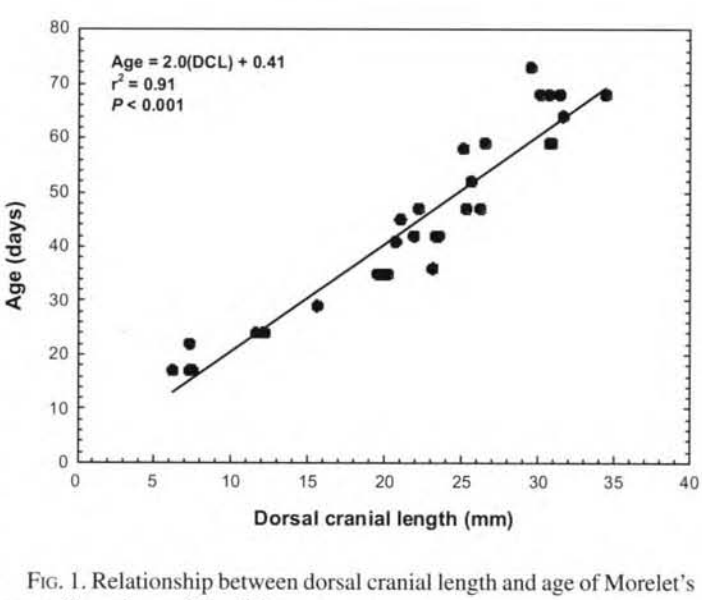

FIG. 1. Relationship between dorsal cranial length and age of Morelet's crocodile embryos (N = 32).

= 0.4–13.6 days), with the greatest deviation occurring in embryos older than 50 days. Some authors have speculated that egg size might affect the relationship between DCL and age (Hall 1985; Webb et al. 1983a, b), and Webb et al. (1983a) recommended scaling morphometric measurements to egg length when calculating linear regression models. We found a significant linear relationship between DCL/EL and embryo age in *C. moreletii* ($r^2 = 0.88$; $P < 0.001$; Fig. 2). Embryo age predicted by this model differed from actual age by an average of 4.5 days (range = 0.25–14 days), with the greatest deviation noted in embryos older than 35 days. However, while the relationship between DCL/EL and embryo age was significant, scaling did not improve the fit of this model. Likewise, Deeming and Ferguson (1990) found EL only affected embryo size during the final stages of incubation and concluded that scaling is unnecessary for developing predictive models. DCL measurements alone thus provide a simple, rapid method for estimating the age of *C. moreletii* embryos.

Although our method is lethal, the sacrifice of a small number of eggs for aging purposes is unlikely to prove detrimental to the fitness of wild crocodile populations. *Crocodylus moreletii* produce large clutches (mean = 25.0 ± 7.6 eggs; range = 9–42; N = 73) and natural losses to predators and flooding are generally high, approaching 100% in some years (Platt 1996). Moreover, eggs and hatchlings are demographically expendable and large numbers are harvested to stock commercial ranches with little effect on natural populations (Rice et al. 1999). Indeed, *Alligator mississippiensis* populations at several lakes in Florida, USA increased over an 11-year period even when 50% of the eggs and hatchlings were annually removed (Rice et al. 1999).

In contrast to previous studies where eggs were collected shortly after oviposition and incubated under constant temperatures in the laboratory (Hall 1985; Webb et al. 1983a, b), our model was derived from embryos developing *in situ*. Incubation temperatures under natural conditions vary both within and among nests, and consequently incubation periods are often highly variable (Deeming and Ferguson 1989; Lang et al. 1989). For example, in an earlier study of *C. moreletii* nesting in Belize, significant differences were found in incubation temperatures between nests, and incubation periods ranged from 61 to 86 days (Platt 1996). Because embryonic development is highly dependant on incubation temperature, incubating eggs under constant temperatures in the laboratory minimizes variation in embryonic development rates and yields predictive equations that are less applicable to field studies (Deeming and Ferguson 1989). Conversely, models derived from embryos collected from wild nests better account for variation in developmental rates, and are likely to more accurately predict embryo age. Therefore, we recommend that future studies develop predictive growth models from embryos developing under natural rather than laboratory conditions.

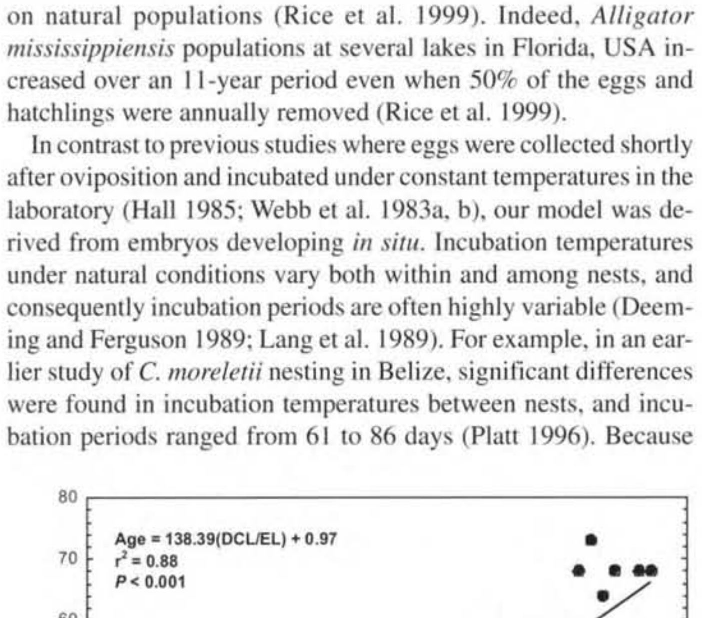

Fig. 2. Relationship between dorsal cranial length/egg length and age of Morelet's crocodile embryos (N = 32).

Acknowledgments.—Robert Noonan allowed access to Gold Button Ranch and provided logistical support during this study. SGP was supported by Wildlife Conservation Society and Clemson University. A Technique for Locating and Recovering Radiotransmitters at Close Range

When radiotracking amphibians, reptiles, and other small vertebrates, determining the location of an animal to within less than a meter is frequently desirable. This is often difficult because most antennas are optimized for locating signals that are several meters to several kilometers away, and because of the complex habitat structure where many small vertebrates are found. For example, one might want to determine the location of a turtle in a large logjam, the position of a snake in a rock fissure, or the site of a frog sitting in a thicket. Being able to locate a transmitter to within centimeters can add valuable information to a tracking study as well as greatly facilitate the recovery of lost transmitters.

When trying to locate a nearby transmitter in locations where a normal multi-element antenna is ineffective, biologists often remove the antenna from the end of the coaxial cable and use the cable as a weak, omnidirectional antenna. Careful sweeps in a grid pattern can sometimes help locate the transmitter in grasslands and similar habitats, but this technique is not practical in many settings. To solve this problem, we have modified and greatly simplified a technique originally used by FWS biologists to recover lost duck transmitters from ponds (anonymous, unpublished FWS report).

Firstly, we modify a coaxial cable by removing the connector at the antenna end of the cable and stripping back the insulation and ground wire sheath about 2 cm. By separating the two wires in the cable, a small omnidirectional antenna is created. We then cut a 75–150 cm length of 1.4 cm (1/2") schedule 80 PVC pipe and seal one end with a PVC cap. The antenna cable is fed into the PVC pipe and the other end is connected to the radio receiver. The modification to the end of the cable creates a small antenna that is much more efficient compared with a plain cable that many biologists use. Although an unmodified cable does detect some radio signals, it does not allow one to localize the signal nearly as well. The use of a PVC pipe allows researchers to probe more easily into crevices and underwater, compared with a loose cable.

We have used this system to locate the exact position of red-legged frogs (*Rana aurora*) during an ongoing study of habitat use. Red-legged frogs often sit in dense vegetation (e.g., cattails, poison oak, blackberry, nettles) or in logjams along creeks. Without the antenna pole, we would only have a general idea of where the frogs were located.

Recovering lost transmitters, or recapturing animals with expiring transmitters, is often a time-consuming part of telemetry studies. The antenna pole is extremely useful for these tasks. Gluing a magnet to the antenna pole with epoxy can facilitate the recovery of transmitters no longer attached to animals. The best magnets for this purpose are rare earth magnets, as they have far more pull (for their size) than ceramic magnets. We currently use a grade 30 neodymium disc magnet (2.5 cm diameter x 1.0 cm high, Catalog number NE150, US $18.00 from Dowling Magnets, 1-800-624-6381, www.dowlingmagnets.com/index1.html), although a wide range of sizes and strengths are available. Note that rare earth magnets are more brittle than standard ceramic magnets, so a thick magnet is preferable. The magnet can be attached to the capped end of the antenna pole so that one can locate and retrieve a transmitter simultaneously. Because we often use our antenna pole for locating animals that we do not want to disturb or capture, we use a separate wooden pole for the magnet.

We bolted a small angle bracket to the end of a broom handle and expoxied the rare earth magnet to the end. The bracket provides a secure attachment to the pole and a good surface for gluing the magnet. A rare earth magnet such as the one we use will pick up (and firmly hold) a small radiotransmitter from ca. 3–4 cm away.

When trying to locate a lost transmitter, we typically use the antenna pole to locate the transmitter as closely as possible. If we happen to bump the transmitter or touch the transmitter antenna, the signal often changes to a slightly higher or lower pitch. We then either reach down and simply pick up the transmitter, or switch to the magnet pole. When using the magnet pole, it is best to monitor the signal; the magnet can cause a notable change in signal (distortion or change of pitch) at close range, or can turn off the transmitter if the transmitter has an internal reed switch. In either case, changes in the signal are a clear indication that the transmitter is within 6–8 cm of the magnet. Of course, the distance over which a change might occur depends on intervening objects (e.g., mud, water, rocks, sticks) and the performance of the transmitter.

We have used the above technique for the last five years and have found lost transmitters in root masses, on the bottom of ponds, in dense cattails, and other difficult situations. Without the antenna pole, we would have spent far more time locating transmittered frogs and we would have frequently obtained only a general location. Additionally, because used transmitters can be refurbished with a new battery for about half the cost of a new transmitter, we have saved thousands of dollars by recovering nearly all our transmitters.

Acknowledgments.—We thank Galen Rathbun for suggesting the technique and providing a copy of the original FWS report. The manuscript benefited from reviews by Steve Bobzien, Joan Fellers, and Galen Rathbun.

A Rapid Technique to Detect Chytrid Infection in Adult Frogs

CANDIDA BRIGGS

Investigations into worldwide population declines in amphibians are under way. A wide range of causes have been identified, e.g., habitat destruction (Ferraro and Burgin 1993a, b) and the introduction of non-native fish (Knapp and Matthews 2000). However, a newly discovered chytrid fungus has been consistently found in mass mortality events in wild populations of frogs in Australia, Panama (Berger et al. 1998), and Spain (Bosch et al. 2001). This is the first known instance of a keratinophilic fungus pathogenic to amphibians. The chytrid fungi present in all of these events were morphologically and ultrastructurally identical and given the name *Batrachochytrium dendrobatidis* gen. et sp. nov. Longcore. To date, there seems to be only the one species but molecular techniques will be needed to confirm this (Berger et al. 1999). The disease caused by *B. dendrobatidis* was called chytridiomycosis (Berger et al. 1998; Longcore et al. 1999).

The fungus has been found inside the keratinized cells of the epidermis of adult or newly metamorphosed animals (particularly the ventral body, limbs, and feet areas); it has also been observed to invade the keratinous teeth of tadpoles (Berger et al. 2000). Histological sections made from frog toe clippings have revealed the fungus to occur within the inner layers of the epidermis, within thickening or erosions of the epidermis, and occasionally within ulcers (Berger et al. 1999). The fungus is predominantly unicellular, spherical or subspherical in shape averaging 15 μm in diameter, with one to several discharge tubes that are usually 2 μm in diameter and range from several microns to 2–4 mm in length. A small percentage of the fungal thalli become colonial following the formation of internal walls (Berger et al. 2000). Fine, thread-like structures (rhizoids) grow out from the base of the fungus through, and out of, the invaded epidermal cells (Pessier et al. 1999).

Skin scrapings, histological sections from toe clippings and elsewhere, transmission and scanning electron microscopy, and immunocytochemistry are all methods that have been used to detect the presence of chytrid fungus in frog skin. All of these have associated problems. Unstained wet mounts (Berger et al. 1999) and Diff-Quick-stained smears of skin scrapings (Pessier et al. 1999) have been used as a first step in determining the presence of the chytrid in host tissue. With this approach the mature zoosporangium could be recognized because of size, shape, and the refractive nature of the fungal wall, but other stages posed problems in differentiation from host cells (Berger and Speare 1998; Pessier et al. 1999). Histological sections stained with haematoxylin and eosin (H & E) are commonly used to confirm the presence of the fungus in the infected animal. Preparation of these sections requires great skill and is a time consuming process. While the H & E dyes used clearly identify the mature zoosporangia, the immature stages can still be confused with nuclei (Berger et al. 2000) or other unicellular organisms, for example protists that are the same size and shape and have the same staining response as the fungus (Pessier et al. 1999). Furthermore, not all sectioned zoosporangia will display the discharge tube(s) and empty zoosporangia can be confused with the various types of ducts from the frog's dermal glands (Berger et al. 2000). The fungal walls in histological sections can also be stained using the periodic-acid-Schiff's reaction (PAS) (Berger et al. 2000), but this staining procedure stains all carbohydrates with 1:2 glycol groups (Pearse 1968) and consequently is not specific for chitin, the principal wall component in chytrid cell walls (Bartnicki-Garcia 1968). Immunocytochemical tests involving polyclonal antibodies have recently been developed to detect *B. dendrobatidis* in lightly infected animals (Berger et al. 2002). While this test reveals rhizoids, walls, internal septa, and zoospores within the frog tissue, it was not specific for *B. dendrobatidis*; other chytrid fungi also gave positive reactions (Berger et al. 2002). However, once again this method is a time consuming and expensive process, because it is used on paraffin-embedded sections involving numerous steps with expensive reagents and requires a reasonably high skill level. All immunocytochemical procedures have inherent problems and require testing of reagent concentrations, pH, temperature of incubation, etc., to determine the correct procedure to avoid non-specific staining (Briggs and Ashford 2001).

To address the above problems we sought to develop a rapid, cost-effective method suitable for non-mycologists to distinguish clearly the chytrid fungus in frogs suspected of being infected with chytridiomycosis. Because the cationic dye Congo red stains cellulose and chitin, and has been used to reveal fungal hyphae in histological sections of human tissue (Slifkin and Cumbie 1988), we investigated the feasibility of this dye to reveal the chytrid fungus in frog skin scrapings and intact skin.

Materials and Methods

We developed and tested our methods on three *Litoria peronii* adults with symptoms of chytridiomycosis that had been frozen following death, 12 *Limnodynastes tasmaniensis* adults that had been preserved in 10% neutral buffered formalin (six of these animals had the chytrid fungus) and 11 *Limnodynastes tasmaniensis* adults that were collected in pitfall traps.

A 0.01% solution of Congo red dye was prepared by dissolving Congo Red Indicator [3,3'-[[Biphenyl]-4,4'-diylbis(azo)]-bis[4-amino-1-naphthalrnesulfonic acid] disodium salt CI 22120] (Merck Art. 1340, CI 22120/360) in phosphate buffered saline (PBS) pH 7.4. The dye was stored in a dark bottle at room temperature and replaced when precipitate appeared. To prepare PBS we dissolved 0.154g of $NaH_2PO_4.2H_2O$, 0.7126g of Na_2HPO_4, and 4.01g NaCl in 500 ml of sterile water.

Each formalin-preserved frog was briefly rinsed with distilled water, and frozen animals were allowed to thaw slightly. A sterile scalpel blade was gently but firmly scraped across the pelvic patch or right inner thigh of each animal. The scraping was smeared onto a microscope slide within a 14 x 12 mm hydrophobic barrier

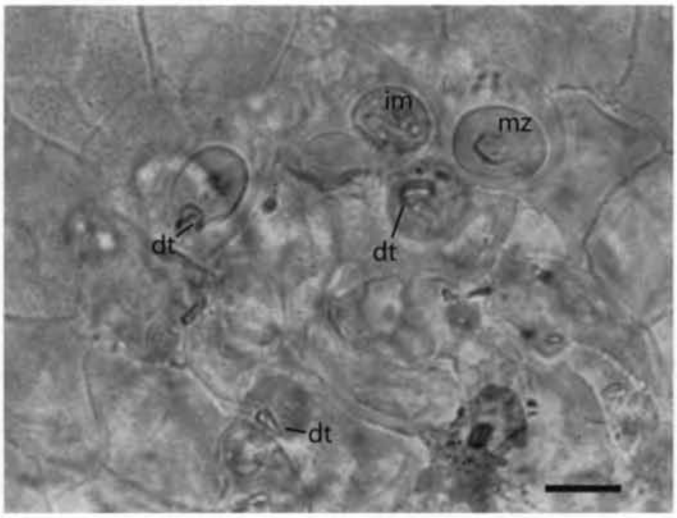

Fig. 1. Skin scraping from a leg of an adult thawed *Litoria peronii*. The emergent discharge tubes (dt) stain brick red after 20 minutes staining. The refractive walls of the mature zoosporangia (mz) are unstained but can be seen against the background. An immature zoosporangium (im) with refractive bodies is also present in the focal plane. Scale bar = 10 µm.

created by using a Liquid blocker super Pap Pen (Daido Sangyo Co Ltd. Tokyo Japan). These samples were air dried for 5 minutes, covered with 60 µl of Congo red solution, stained for 10, 20, 30, or 60 minutes, then covered with a 22 x 40 mm coverglass. If the stain dries out, crystalization of the salts will occur.

Small (4 x 6 mm) pieces of unpigmented skin were cut from the ventral surface of the inner left thigh of each preserved animal; these were scraped, rinsed with distilled water, and placed onto a clean glass microscope slide. The pieces of skin were covered with the Congo red solution, stained for 10, 20, 30, or 60 minutes, rinsed with distilled water and examined.

Scrapings taken from live animals in the field were obtained with a small sterile plastic spoon (attached to the lid from a 76 x 20 mm feces tube from Sarstedt 80.734.301). This spoon was scraped over the inner thigh and the underside of the feet. The spoon and scraping was put into the vial containing 200 µl of PBS, transported back to the laboratory in plastic bags surrounded by ice. The entire scraping solution was deposited inside a 14 mm x

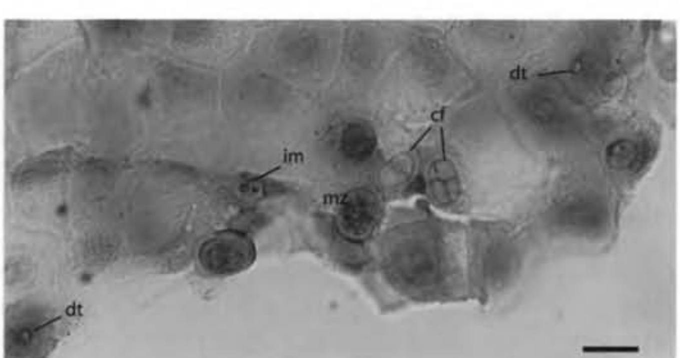

Fig. 2. Skin scraping from a preserved *Limnodynastes tasmaniensis* adult 60 minutes after staining with Congo red. The walls of the immature zoosporangia (im), colonial forms (cf), mature zoosporangia (mz), and discharge tubes (dt) are well stained. The frog nuclei are lightly stained. Scale bar = 10 µm.

25 mm hydrophobic rectangle created on a clean microscope slide. After most of the solution had been evaporated, the scraping was covered with 80 µl of the dye, stained for 60 minutes, covered, and examined.

Results and Discussion

The keratinized epidermal cells could not be confused with the chytrid fungus. In both *Limnodynastes tasmaniensis* and *Litoria peronii* the epidermal cells were flat, 4–6 sided polygons with a single round or oval nucleus (4.5–7 x 7.5 µm) and no refractive bodies (Figs. 1, 2). There was no alteration in shape or size following preservation in formalin or freezing. The cell membrane did not stain with Congo red, although the nucleus stained in damaged cells.

The skin scrapings from infected and non-infected animals resulted in sheets of keratinized epidermal cells, clusters of subepi-

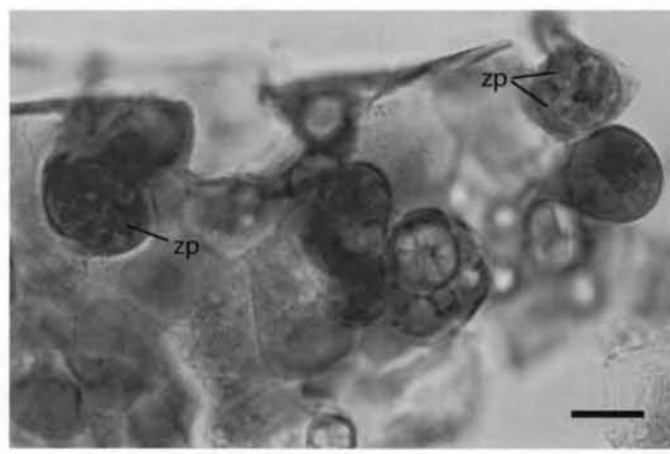

Fig. 3. Skin scraping from a preserved *Limnodynastes tasmaniensis* adult 60 minutes after staining with Congo red. The mature zoospores (zp) can be seen through the stained wall of the zoosporangia. Scale bar = 10 µm.

dermal cells, isolated cells, and nuclei; fungal spores and hyphae were occasionally present. When smears from uninfected formalin-preserved animals were stained for between 10 and 60 minutes, the nuclei of the subepidermal cells were stained orange, but nuclei in the epidermal cells were only stained orange when the cell's plasmalemma had been breached. The stained nuclei in the epidermal cells were still readily distinguishable from the fungus. When smears from infected animals were stained for 10 minutes, there was no staining of the fungus. After 20–30 minutes, the walls of all empty zoosporangia and the exposed discharge tubes of mature zoosporangia were stained a distinctive brick-red color but the dye did not penetrate the intact plasmalemma to stain the immature stages or the host nuclei (Fig. 1). However, the immature stages could still be recognized inside intact epidermal cells (Fig. 1) and distinguished from the host nucleus by the presence of many, small to medium-sized refractive bodies, the clear zone surrounding them, and a thin wall. Often more than one zoosporangium was in the same cell. After a longer staining period (i.e., 45–60 minutes), the walls of the majority of immature, mature, colonial, and empty zoosporangia were stained a brick-red color and the

host nuclei were stained a paler orange (Figs. 2 and 3). It is not possible to say whether the staining in these circumstances was because of an initial breach in the cell plasmalemma or a breach resulting from the prolonged staining in the dye. However, trials in which the dye had been dissolved in distilled water or phosphate buffer were not as successful. The staining time required was at least two to three times longer, the walls of the immature stages did not stain, and the intensity of the color was less.

Skin scrapings from the live animals contained small sheets of epidermal cells, soil debris, unicellular and colonial green algae, fungal hyphae and spores. Although the algal cells were similar in size and shape to the chytrid fungus, they did not have the numerous refractive bodies found in the immature zoosporangia nor the discharge tubes found in the mature zoosporangia: they were also green in color. The colonial algae were easily distinguished from the colonial chytrid fungus, again by the green color as well as by the lack of binding of the dye. The mucilage surrounding living algal cells prevents the penetration of Congo red to the wall beneath and the mucilage does not stain. The fungal spores present were not similar in size or shape to the chytrid fungus and many were naturally pigmented brown (not shown).

In all of the skin scrapings, the hydrophobic barrier was successful in retaining the scraped off cells on the slide. When sheets of cells became trapped on top of the hydrophobic barrier after the lowering of the coverslip, the chytrid zoosporangia were still easily seen because they had already been stained with Congo red.

These simple procedures were very cost effective in time (ca. 1 h for preserved/frozen animals) and materials relative to other procedures such as histological sections, TEM, immunocytochemistry. Although the dye will be absorbed by the host nuclei and other structures such as muscle fibers, the color is less intense and quite different to the color produced when it binds to the wall of the chytrid fungus. Congo red might thus be considered a useful dye to detect the fungus within the host tissue as well as distinguish it from other unicellular organisms. While the extent of the chytrid infections of an animal is better achieved through examination of the whole skin mounts, the scraping technique successfully collects infected cells. It might be applicable to all living amphibians, especially those where toe-clipping is not feasible, and could be successfully incorporated into monitoring or ecological studies to check for the spread of the chytrid fungus in frog populations. The scraping of preserved museum animals would allow collections to be quickly checked without apparent damage to the specimens.

A New Underwater Trap for Catching Turtles

GERALD KUCHLING

Department of Zoology, The University of Western Australia
Crawley, WA 6009, Australia
e-mail: kuchling@cyllene.uwa.edu.au

Cylindrical, collapsible, baited hoop nets have been used to catch freshwater turtle for decades (Legler 1960; Plummer 1979). The basic design has been modified because of the availability of new materials (Feuer 1980), and hoop traps have been combined with a separate holding section to reduce turtle escapes (Kennett 1992). Iverson (1979) described a cheaper, baited, aquatic trap with the shape of a rectangular box made of chicken wire that was also combined with drift fences to catch turtles during terrestrial movements (Iverson 1991).

A common feature of traditional hoop traps is that they either require placement in shallow water to allow captured turtles to breath at sections of the trap that protrude into the air, or, if set in deep water, they must be checked frequently to prevent turtles

from drowning. This limits the trap's usefulness in catching large, highly aquatic turtles (for example *Elseya dentata* and *Erymnochelys madagascariensis*) that prefer deep water. To some degree this problem can be overcome by constructing tall chicken wire traps, but those traps cannot be easily collapsed and require a lot of space during transport.

Here I describe a collapsible trap with a rectangular frame and netting. Approximately 2.8 m of 1 m wide stretched netting with knotted or knotless 30 mm (stretched) mesh is required per trap. A rectangular 10 mm aluminum rod or tube frame of 80 x 60 cm forms the base. Two half-rectangle aluminum bars are hinged to the middle of the long sides of the base frame. These bars give stability to the two entry funnels when the trap is set (Fig. 1) and lie neatly on the frame when the trap is collapsed. Two strong cords are tightened to and stretch between the sides of each half-rectangle bar to form the entry slit of the funnel. The netting is stitched to the bottom frame and the funnel sections. Along the slit of the funnel the net is threaded to the cords that stretch between the sides of each bar. The two entries of the trap are thus formed by narrow, elastic slits of 60 cm length (Fig. 1). Netting is stitched from the base of the frame and the bars to form a cylindric section that extends upwards. The vertical cylindrical net section is tied shut on top with cord to close the trap and is untied when necessary to allow removal of turtles (Fig. 2). The material and construction cost per trap is US$ 40–50, which is higher than the cost of hoop nets or chicken wire traps because more netting and some welding is necessary.

Traps are transported in the collapsed state, and typically five to ten traps are strapped together or carried in a canvas bag. Traps are set and held open by stretching a cord along the mid-line between the two movable bars which holds the bars and the two entry funnels in place. If bait is used it is enclosed in wire mesh and/or fly-screen mesh and knotted to the centre of the stretch-cord (Fig. 1). The bait is suspended in the middle between the entry throats and touches neither the bottom nor the side netting. Because of the weight of the aluminum frame, traps sink underwater. Traps are set so that they rest on the bottom or touch slopes or tree trunks. The upper end of the vertical cylindrical net section is tied with a cord to a tree branch or a stake above the water surface to allow trapped turtles access to air for breathing. Plastic floats can be placed inside the net to ensure that its top always

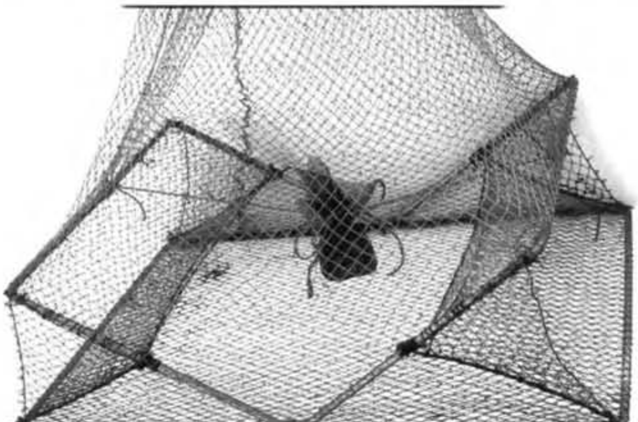

FIG. 1. Close up of frame section of erected turtle trap with bait.

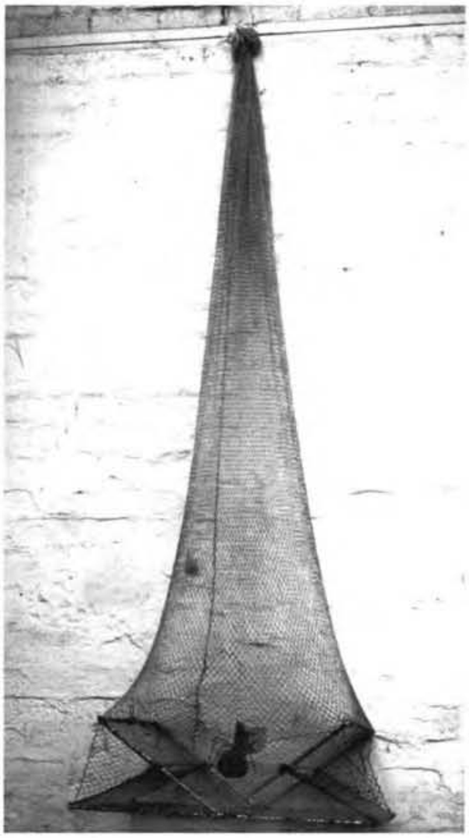

FIG. 2. Hanging turtle trap ready for positioning in deep water.

remains above the water surface. Because the upward reaching cylinder stretches when the trap is suspended (Fig. 2), traps can be set at a water depth of about 2 m and trapped turtles will still have access to air.

About 60 of these traps have been used in freshwater turtle field studies in Western Australia since 1994 and in Madagascar since 1996. Several thousand turtles of the genera *Chelodina*, *Elseya*, *Emydura*, *Erymnochelys*, *Pelomedusa*, *Pelusios*, and *Pseudemydura* have been caught. If traps hang in deep water, it is important to use stakes or submerged tree trunks to stabilize them. Once ten large turtles had entered one trap that was checked every 12 hours. The trap was quite congested with turtles, and their movements caused the vertical net to rotate and twist. Three of the ten turtles were trapped in the lower part of the net under the twisted section and were unable to reach the air. Although all turtles recovered and survived, the accident demonstrates the importance of securing the traps so that they cannot rotate and the vertical net compartment cannot be twisted. Small crocodiles (*Crocodylus niloticus*, *C. johnsoni*, < 1.2 m total length) sometimes entered the traps and in two instances a *C. johnsoni* entangled its long snout and teeth in the net and could not reach air. The crocodiles seemed at first drowned, but both recovered some minutes after removal from the traps.

Long-necked turtles of the genus *Chelodina* show high escape rates from conventional baited hoop nets without a separate holding section (Kennett 1992). When trapping medium-sized turtles such as *Chelodina*, I constrict the funnel slits in the middle with a piece of wire or string to tighten the entries further by creating two slits of 30 cm length rather than one of 60 cm. Theoretically, a holding compartment (Kennett 1992) could also be added to the trap described here.

The critically endangered Western Swamp turtle (*Pseudemydura umbrina*) in southwestern Australia does not enter baited traps (Burbidge 1981; pers. obs.). Terrestrial drift fences with pitfall traps around swamps were used to catch *P. umbrina* during the 1960s and 1970s (Burbidge 1981), but because of predation of trapped turtles in the pits by introduced foxes (*Vulpes vulpes*), drift fence trapping was discontinued in the early 1980s. Less than 50 wild individuals of *P. umbrina* survived into the 1990s, a situation requiring capture techniques that minimize risk to individuals. Since 1994 I combined the traps described here with drift fences (10 mm black plastic mesh) to catch *P. umbrina* in seasonal swamps. I use drift fences only in water, with traps joined to the drift fence by threading a metal stake through netting as well as fence mesh. With this set up, turtles entering traps remain in the water and are not subjected to desiccation, direct solar radiation, or predation. Because of the height of the net, the risk of drowning turtles when water levels suddenly rise due to flooding is eliminated. The traps worked best when the water was deep enough to cover the throat of the trap. Because the traps lie flush with the substrate and the bars can be positioned lower if necessary, the traps can be set in shallower water than most conventional traps. Vogt (1980) described the use of unbaited fyke nets with long leads as underwater "drift fences" to catch turtles. Fyke nets obviously are suitable to catch turtles in rivers, lakes, and ponds, but in shallow swamps with fluctuating water levels drift fences with the traps described here are more suitable. They are currently the only acceptable and successful trapping method for *P. umbrina*.

There are many advantages of the new trap design: When collapsed the traps are flat rectangles that can easily be stacked and bundled together. In contrast to hoop nets, stretchers or stiffeners in the form of wooden dowels or stakes with hooks are not necessary. The traps are easy to transport, even in small boats or when hiking over difficult terrain. Traps can be used with bait and positioned underwater shallowly or relatively deeply (about 2 m). They are particularly useful for trapping large, aquatic swimming and bottom-walking species that may be reluctant to enter shallow water. The narrow entry slit of the funnels is a less likely escape route for turtles than the round or elliptical openings of hoop traps. The traps are useful to trap hatchlings as well as large turtles. Finally, unbaited traps can be combined with drift fences in shallow water and under changing water levels.

Quantitative Sampling of Stream Salamanders: Comparison of Dipnetting and Funnel Trapping Techniques

JOHN D. WILLSON

and

MICHAEL E. DORCAS

Department of Biology, Davidson College
Davidson, North Carolina 28036, USA
e-mail (JDW): willson@srel.edu; (MED): midorcas@davidson.edu

In recent years, increased awareness of amphibian declines has resulted in widespread efforts to inventory and monitor amphibian populations, thus initiating the development of standardized and quantitative sampling techniques. Accepted sampling methods for aquatic adult and larval amphibians include dipnetting, seining, and funnel trapping (Heyer et al. 1994). Numerous types of funnel traps have been employed and include simple wire minnow or eel traps (Fronzuto and Verrell 1999), expensive, species-specific traps (Mushet et al. 1997), and traps made from plastic jugs or soda bottles (Calef et al. 1973; Griffiths 1985; Richter 1995; Smith and Rettig 1996). While funnel trapping has proven to be a valuable technique for amphibian sampling in many lentic habitats, it has seldom been applied to lotic ecosystems.

The most widely accepted method for sampling lotic habitats for amphibians is timed dipnetting (Shaffer et al. 1994). Dipnetting, while effective for sampling some amphibian species, is sometimes difficult to standardize because of variation in effort among investigators. Partly because of a lack of standardized sampling techniques, stream-dwelling amphibian populations have not been monitored as closely as those in other habitats (Heyer et al. 1994). Here, we describe an inexpensive and quantitative method for sampling stream-dwelling salamanders using funnel traps constructed from plastic soda bottles. This technique, employed in small streams in the western Piedmont of North Carolina, yielded a greater diversity of salamander species and life-stages than did dipnetting.

Funnel traps were constructed from 3.0 L, 2.0 L, 1.0 L, and 0.6 L plastic soda bottles as described by Griffiths (1985). A range of bottle sizes were used to trap various microhabitats within streams. Larger (3.0 L and 2.0 L) bottles were used in stream pools and other deep-water areas while smaller bottles allowed trapping in shallow water along stream edges and were especially effective in trapping undercut banks, along submerged logs, and other areas frequented by adult salamanders. To create each trap, the top of the bottle was cut off and inverted. Holes were punched, using a metal single-hole punch, through the top and bottom of the trap mouth and a bamboo garden stake was passed through the holes to hold the inverted bottle top in place. The trap was anchored horizontally to the streambed by pushing the stake into the substrate. Traps were set in water slightly shallower than the diameter of each bottle, resulting in a layer of air inside of each bottle.

To test the efficacy of funnel trapping in small streams, we trapped a total of eight streams located within 11 km of Davidson, North Carolina. Each stream was trapped for two, one-week sessions, once in mid-February and again in mid-April 2001. During

each trapping session, 12 traps were set approximately 1 m apart along the stream edge and in slow-current areas where leaves and debris had collected. Traps usually were set facing into the current and were not baited. Each set of 12 traps contained one 3.0 L, four 2.0 L, three 1.0 L, and four 0.6 L bottles to allow for trapping in a variety of depth and current velocity locations. Traps were checked every other day during each week-long trapping session, at which time all animals found in the traps were removed. No in-trap mortality was observed. After checking, traps were moved a short distance (< 1 m) to ensure thorough trapping of all microhabitats within the stream. All salamanders captured in traps were taken to the laboratory for the remainder of the one-week trapping session to avoid recaptures and were subsequently released.

We compared the effectiveness of funnel trapping to timed dipnetting, the method recommended by Shaffer et al. (1994) for sampling amphibian larvae in streams. Dipnetting was conducted for two 2-day periods during the trapping period (late February and mid-April). During these periods, each of the eight streams was netted for a period of 30 minutes per stream. Netting concentrated on areas of submerged leaves, rocks, logs, and other cover objects and was confined to underwater microhabitats (Shaffer et al. 1994).

Funnel trapping and timed dipnetting both yielded high numbers of salamanders; however, trapping yielded a greater diversity of species and life-stages than dipnetting (Fig. 1). Dipnetting produced high numbers of *Desmognathus fuscus* and *Eurycea cirrigera* but the vast majority (97%) were larvae. Funnel trapping also yielded high numbers of *D. fuscus* and *E. cirrigera*, but with a much larger percentage (27%) of adult salamanders (Fig. 1). In addition, we captured three *Pseudotriton ruber* larvae and five adult anurans, of three different species (*Rana clamitans, R. catesbeiana*, and *Pseudacris triseriata*), in funnel traps. Of these species, only *R. catesbeiana* also was detected by dipnetting.

We estimated the time required to construct, set, and check the funnel traps used in this study and compared it to the time re-

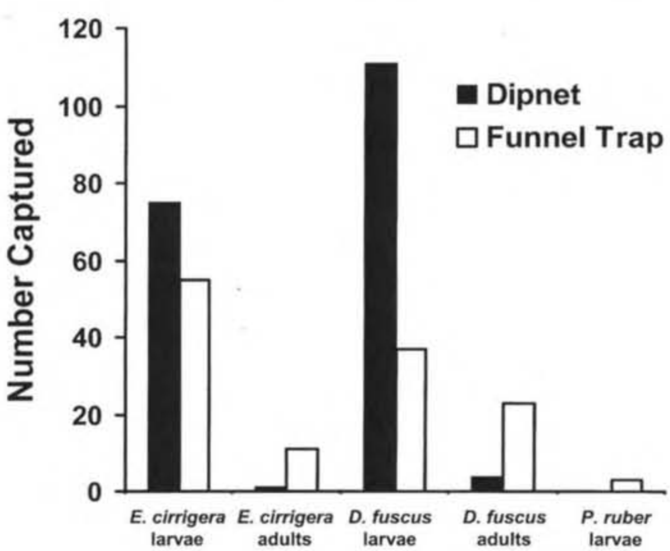

FIG. 1. Species and life-stage composition of salamanders captured by funnel trapping and by dipnetting. Note that while dipnetting yielded a greater total number of salamanders, funnel trapping captured many more adult salamanders. In addition, *Pseudotriton ruber* was detected only by funnel trapping.

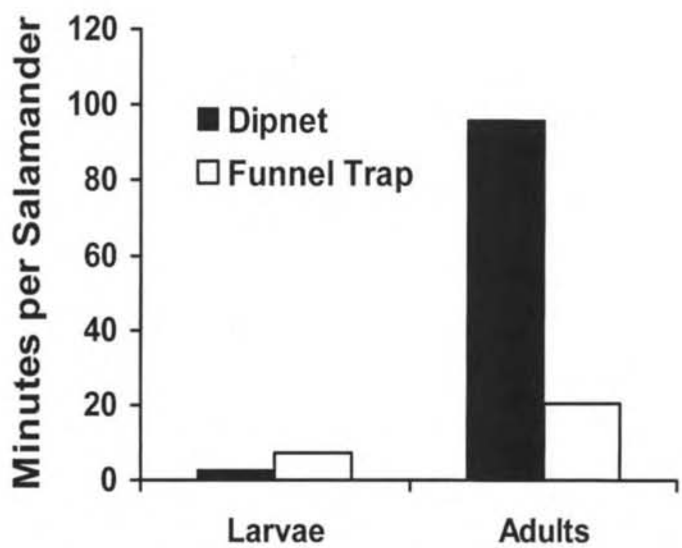

FIG. 2. Average time invested per salamander captured for funnel trapping and dipnetting. Note that while dipnetting captured more salamander larvae per unit of time, funnel trapping was much more efficient for capturing adult salamanders.

quired for dipnetting. Although time invested per salamander larva was lower for dipnetting, funnel trapping was much more efficient in capturing adult salamanders (Fig. 2). In addition, over the two-month study period, dipnetting only sampled each stream at two time points, while funnel trapping sampled each stream continuously over two week-long periods. This is important, considering that many amphibian species are only active at night or under specific climatic conditions (Peterson and Dorcas 1992). Finally, the cost of these funnel traps is negligible when compared to standard wire funnel traps, which generally sell for about US $10 each.

We demonstrate that utilizing funnel trapping in small streams in the western Piedmont of North Carolina yielded a greater diversity of amphibian species and much higher numbers of adult salamanders than dipnetting. Thus, this technique offers an inexpensive complement to traditional lotic sampling techniques in the surveying and monitoring of amphibian populations.

Acknowledgments.—We thank A. Tuscano and M. Seifert for conducting initial testing, landowners F. Bragg, P. Zimmerman, L. Davis, J. Tevepaugh, and the Runny Meade Equestrian Center for use of their property. J. Sealy, K. Grayson, and D. Stroupe provided useful advice on the manuscript. Reconstructing Thermochron iButtons to Reduce Size and Weight as a New Technique in the Study of Small Animal Thermal Biology

KYLIE A. ROBERT
and
MICHAEL B. THOMPSON
Heydon-Laurence Zoology Building (A08)
School of Biological Science and Institute of Wildlife Research
The University of Sydney, NSW 2006, Australia
e-mail (KAR): krobert@bio.usyd.edu.au

Recent developments in small electronic temperature recorders designed for use in the food industry have the potential to revolutionize the collection of thermal data in small animals. Collecting temperature data in small reptiles is most often restricted to laboratory studies in thermal gradients (Greenberg 1976; Licht et al. 1966; Sievert and Hutchison 1991), by the use of physical models placed in the field (Hertz 1992; Porter et al. 1973), or by inserting a cloacal thermocouple/thermometer soon after capture in field studies (Avery 1982; Schwarzkopf and Shine 1991). Thermal gradients measure selected thermal preferences in an artificial environment, models estimate operative temperatures in the field, and cloacal thermocouple/thermometer measurements in field studies can only measure active individuals or those that take refuge in accessible areas. Each of the above techniques alone does not provide a true representation of the animal's "natural" or "field" thermal biology, particularly in periods of inactivity, hibernation or within inaccessible refugia.

With modification, the DS1921 Thermochron iButtons manufactured by Dallas Semiconductor (Texas, USA) (www.ibutton.com/ibuttons/thermochron.html), a small lightweight real time and temperature recording device, can be attached externally or implanted internally into small animals. The unmodified DS1921 Thermochron iButton weighs approximately 3.0 g, is 17 mm in diameter and 6 mm in thickness. By disassembling units and then reconstructing without the external stainless steel housing, the weight can be halved to approximately 1.5 g or less and the dimensions reduce to the size of the circuit board which is 14 mm in diameter and the thickness depends upon the new battery size.

The DS1921 Thermochron iButton integrates a thermometer, real time clock and memory for storing temperature readings. It accurately measures temperatures ± 1°C from as low as –20°C to +85°C in 0.5°C increments. Temperature readings are available in two formats which run concurrently 1) time vs. temperature mode that records temperature and date-stamps when it occurred, 2) histogram mode that measures the frequency of temperature in 2°C increments rather than specific times of occurrence. The DS1921 Thermochron iButton can log up to 2048 consecutive temperature readings in read-only memory, after which readings can be either stopped or enabled to roll over. The histogram mode has 63 bins of memory set at 2°C intervals, and each bin can store 65,000 readings (Greaves 1999). The DS1921 Thermocron iButton's can be launched and downloaded with the use of a reader (Blue Dot Receptor®) connected to an existing PC computer with free software downloaded from Dallas Semiconductor (available at www.iButton.com). Recordings are made at user defined time and rates, with a maximum start delay of 45 days and recording rate ranging from 1 every minute to one every 255 minutes. The life expectancy of the DS1921 Thermochron iButton is more than 10 years or greater than 1 million samples, whichever occurs first (Greaves 1999). To date, our reconstruction of the DS1921

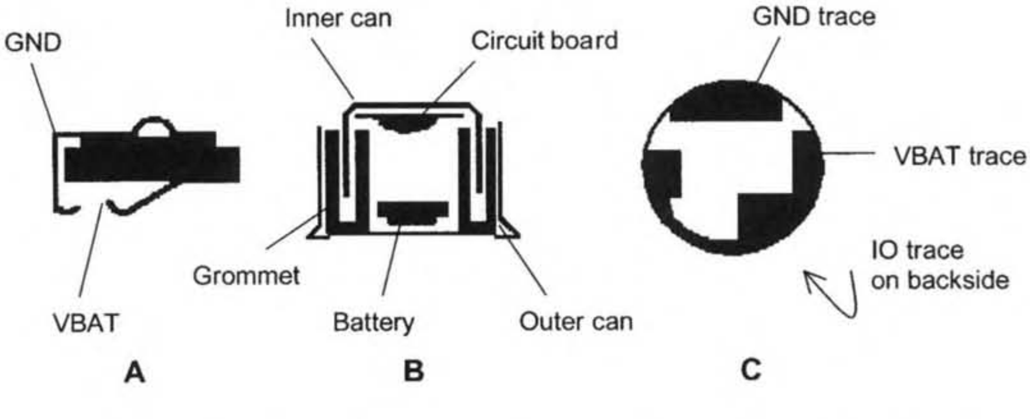

FIG. 1. Construction of the DS1921 Thermochron iButton, (A) Battery (B) Complete unit (C) Circuit board. See text for explanation of components.

Thermochron iButton has not altered the performance or the life expectancy and not a single unit has failed.

Construction of the DS1921 Thermochron iButton.—The DS1921 Thermochron iButton is constructed (Fig. 1) of two stainless steel cups that make up the housing separated by a plastic grommet. The plastic grommet isolates the IO (data) and GND (ground) sections of the circuit board externally and the VBAT (power) and GND connections internally. Springs are welded to the positive and negative terminals of the battery. It is important that the positive and negative terminals do not touch or the battery will short out causing rapid battery drain. The battery "snaps" into the plastic grommet. The circuit board is positioned in the bottom of the inner housing with the crystal facing up. The semicircle trace on the front side of the circuit board is VBAT. The other large trace is GND, corresponding to the springs on the battery. The back of the circuit board is one large IO trace, which makes contact with the bottom of the inner housing. The grommet and battery slides on top of the inner housing with the VBAT and GND terminals aligned. This combination then slides into the outer housing and the GND battery spring makes contact to the outer housing. The outer housing is crimped over the grommet and inner housing, holding the construction together.

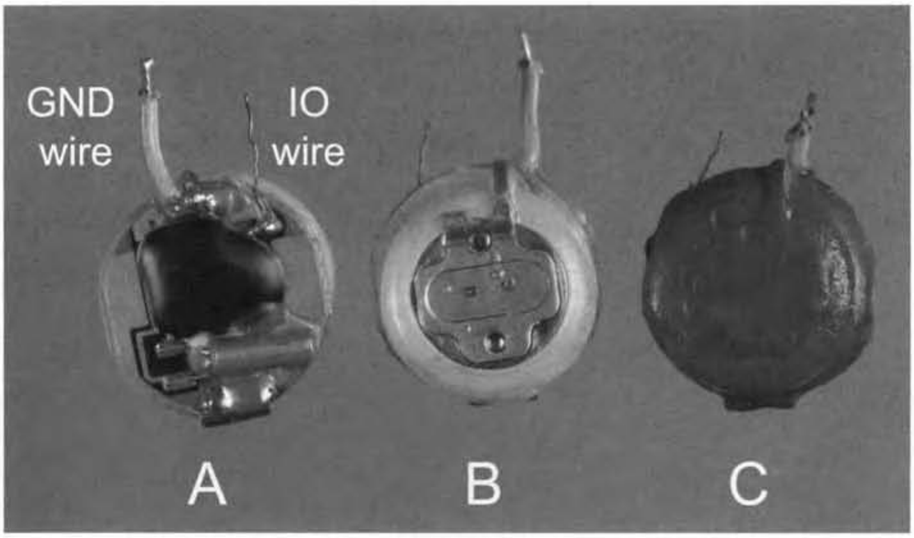

FIG. 2. Reconstructing the DS1921 Thermochron iButton without housing (A) Circuit board soldered to battery with rigid exposed wires attached (B) Insulated battery soldered to circuit board viewed from above (C) Modified unit complete and coated in red Plastidip®.

De-housing of the DS1921 Thermochron iButton.—To reduce the size and weight of the DS1921 Thermochron iButton for use on small animals the iButton can be opened to remove the internal components and reconstructed without the stainless steel housing that accounts for a large proportion of the weight. A vise should be used to hold the DS1921 Thermochron iButton and a small tooth hacksaw (32 teeth/inch) can be used to make vertical cuts through the outer housing in 3 or 4 evenly spaced cuts around the housing. By using a pair of needle nosed pliers, the outer housing can be pulled away from the inner, not unlike pealing a banana.

Reconstruction of the DS1921 iButton without the housing.—Outside of the housing the circuit board should be soldered to the battery (Fig. 2). To avoid damage to the battery it is best to use new batteries with solder tabs attached which are available upon request from most major battery suppliers. The DS1921 uses a 3 Volt lithium BR1225 battery; a smaller battery such as BR1216 or CR1025, can be substituted, but they have a shorter lifetime. The bottom tab is VBAT and the tab that comes over the top of the battery is GND. If the battery is not insulated, a piece of plastic tape should be used to prevent the GND tab touching the side of the battery which would cause the battery to short. It is important to line the tabs up with the traces on the circuit board and solder them.

To attach the unit to the reader (Blue Dot Receptor®) a rigid wire needs to be soldered to the IO trace and another to the GND trace on the reconstructed unit (Fig. 2). One wire should be thicker in diameter or color coded for easy identification when attaching to the reader. These two wires provide exposed leads for attachment to the reader (Fig. 3). The wire attached to the IO trace connects to the inner contact on the reader and the wire attached to the GND trace connects to the outer contact on the reader. To connect the unit to the reader, one end of a wire needs to be coiled around the inner contact of the reader and the other end with a small alligator

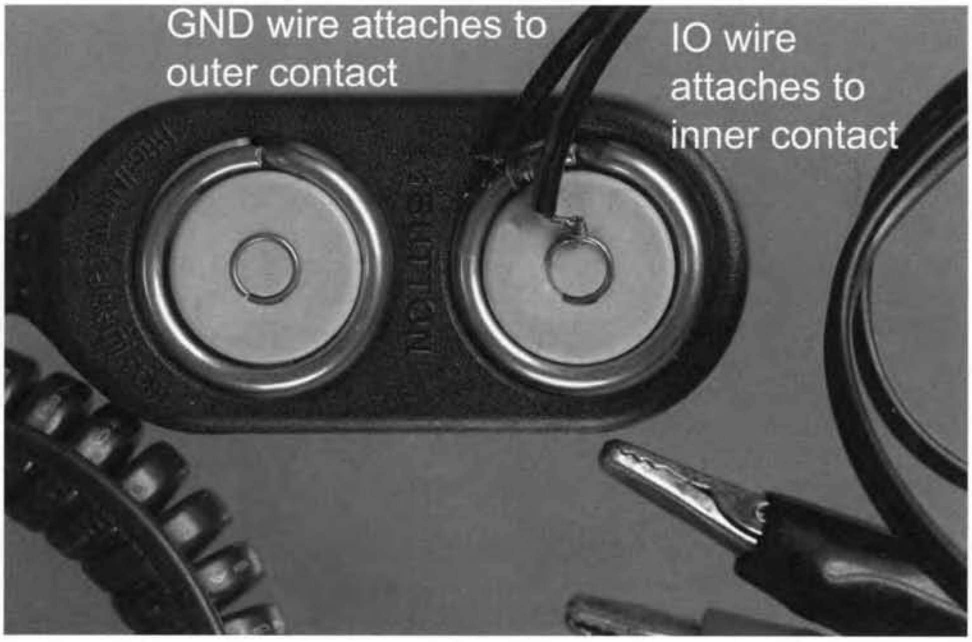

FIG. 3. Reader (Blue Dot Receptor®) showing wires coiled around contact points that then attach to exposed leads on the modified units via alligator clips.

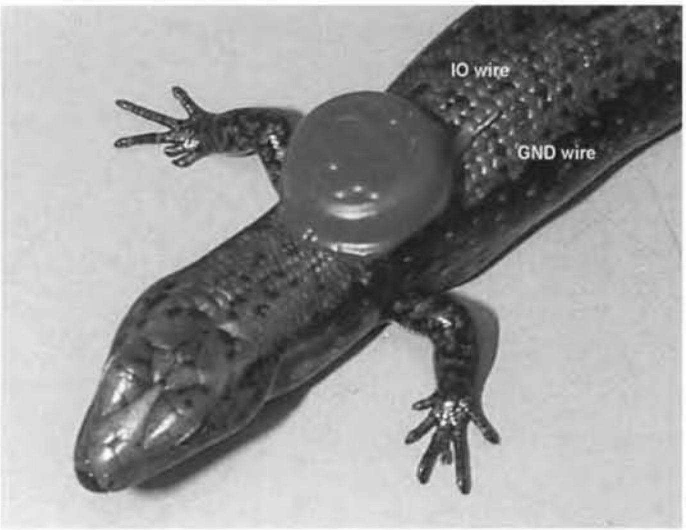

FIG. 4. A female *Eulamprus tympanum* fitted with a modified Thermochron iButton.

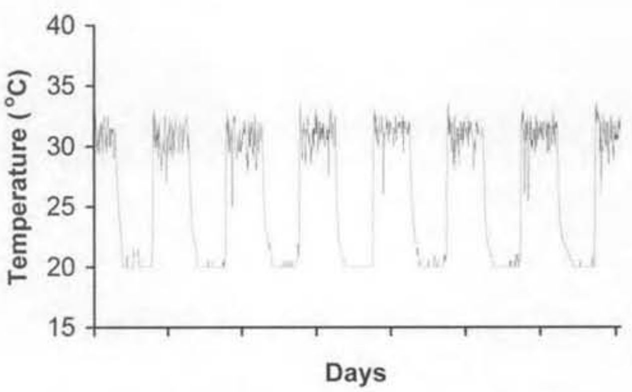

FIG. 5. Thermal profile of a captive female *Eulamprus tympanum* over one-week at a 5-minute sample rate.

clip can then be attached to the exposed IO wire on the unit. Another wire should be coiled around the outer contact of the reader with the opposite end attached to the exposed GND wire on the unit also with a small alligator clip (Fig. 3). After testing the soldered unit, it should be sealed to ensure it is watertight with Plastidip™ (Minnesota, USA) (www.PLASTIDIP.com) with the exposed ends of the IO and GND wires emerging from the Plastidip™ (Fig. 2).

We tested the modified unit on six gravid female *Eulamprus tympanum* over several weeks in laboratory enclosures. Lizards were housed individually in 620 x 400 mm enclosures with 20–30 mm depth of soil, flat rocks and leaf litter for shelter. Lizards were provided with heat from 100 W incandescent bulbs at one end of their enclosure to allow them to thermoregulate. Enclosures provided a thermal gradient of 20 to 40 ± 1°C during daylight hours and 20 ± 1° C during the night. The modified units where attached to the backs of lizards with Super Glue™ (cyanoacrylic glue) behind the head, between the shoulder blades (Fig. 4) and gave continuous measurements of temperature at 5-minute. intervals (Fig. 5). Measurements can be downloaded and units can be re-launched while the unit remains attached to the animal. The unit will detach from reptiles upon shedding or acetone can be applied to the site of attachment to remove the unit prior to shedding.

Acknowledgments.—I thank Patrick Evans from iButton support, Joerg Suckau and Basil Panayotakos from the School of Biological Sciences workshop for technical advice. Lizards were collected under scientific licence from the New South Wales National Parks and Wildlife Service (B2082) and research was approved by the University of Sydney Animal Care and Ethics Committee (L04/10-98/1/2855). The project was supported in part by an ARC Large Grant to M. B. Thompson and by an Ethel Mary Read Research Grant from the Zoological Society of New South Wales to K. A. Robert.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 34, Number 1 (March 2003).

CAUDATA

AMBYSTOMA TIGRINUM **(Tiger Salamander). PREDATION.** Although a wide variety of birds have been documented or implicated as predators of *Ambystoma tigrinum* (Lannoo and Phillips, *in press*. *In* M. J. Lannoo [ed.], Status and Conservation of U.S. Amphibians. Univ. California Press, Berkeley), most of the species target aquatic larval forms. On 19 June 2001 in Taylor County, Georgia, USA, I encountered a cache of numerous animals impaled on a barbed-wire fence by loggerhead shrikes (*Lanius ludovicianus*). Herpetofauna found among the cache included several adult *Hyla squirella* and *H. cinerea*, and one post-metamorphic *A. tigrinum*. Although amphibians have been reported in the diet of loggerhead shrikes (Yosef and Grubb 1993. Condor 95:127–131), I believe this is the first reported observation of loggerhead shrikes predating a salamander.

New Records and Natural History Notes for Amphibians and Reptiles from Southern Morocco

PATRICIA A. HERRMANN
and
HANS-WERNER HERRMANN
Center for Reproduction of Endangered Species
Zoological Society of San Diego, P.O. Box 120551
San Diego, California 92112-0551, USA
e-mail: hwherrmann@sandiegozoo.org

In an historical context, Morocco has been suitably explored with herpetological expeditions dating back to Gervais (1835). The distribution of amphibians and reptiles in Morocco is thoroughly outlined in the herpetofaunal atlas by Bons and Geniez (1996); this atlas is used as a primary reference in this paper. The following is a composite of significant findings from five months of data gathered in southern Morocco during the periods of May–July 1985, October 1999, and September–October 2000. Such has resulted in notable range extensions for six species of lizards and three species of snakes and several novel comments on natural history. Voucher specimens were deposited in the Zoologisches Forschungsinstitut und Museum Alexander Koenig (ZFMK), Bonn, or the Hessisches Landesmuseum (HLMD), Darmstadt, Germany. Localities were determined by the use of a handheld Garmin© global positioning system (GPS) device or by the use of maps. Specimen identification relative to range extensions were confirmed by Wolfgang Böhme, Zoologisches Forschungsinstitut und Museum Alexander Koenig, Bonn.

Anura

Bufo brongersmai – Tafraoute, 29°43.30'N, 8°58.76'W, 11 October 1999. At ca. 2100 h hundreds of animals were encountered in the flat-packed sand basin between the rocky hills adjacent to the town. The toads were active and orienting apparently at random, along with equally abundant *Bufo viridis* and numerous *Bufo mauritanicus*. This was after the second day of heavy rain following what locals reported as a two-year drought. No amplectant pairs were observed. No standing water was encountered. In Tafraoute on 18 June 1985, during the dry summer period, only one toad was found. It was located at night under plants which were routinely watered and was within the town limits. On 9 and 10 October 2000, two nights of searching at the Tafraoute locality revealed no toads. This was also during an extended dry period. This illustrates the periodic abundance of this reportedly rare toad species (Bons and Geniez 1996).

Lacertilia

Stenodactylus petrii – Oued Tissinnt, ca. 5 km E of Mrhimina, 29°49.14'N, 7° 08.18'W, 5 October 2000. This area is characterized by low-lying sand dunes interspersed with lava flows and large lava boulders. Two specimens were collected while searching the Oued Tissinnt dunes at night (ZFMK 73504: SVL 50 mm, TL 97 mm; ZFMK 73505: SVL 38 mm, TL 72 mm). This find extends the range of this species by ca. 100 km to the west and is the first reported locality away from major sand dunes. Dry riverbed routes may be used by this psamnophilous species as dispersal pathways.

Stenodactylus sthenodactylus – Tendrara, ca. 9 km N of the town, 33°05.05'N, 1°59.27'W, 4 October 1999. This male specimen (ZFMK SA2001:1) was found during the day, in a flat, hard-packed sand desert, under a rock. This find extends the eastern range of this species by ca. 50 km in Morocco, thus bringing it to the Algerian border.

Ptyodactylus oudrii – Oued Tissinnt, ca. 5 km E of Mrhimina, 29°49.14'N, 7°08.18'W, 5 October 2000. This gecko is cited in the literature as a dweller of steep and smooth rocks, boulders, and cliffs (Bons and Geniez 1996; Schleich et al. 1996). Here we report the use of a tree as a habitat for this species. A night search revealed two specimens ca. 1.6 m above ground in an *Acacia* tree. Ants, which are a prey item of this species, were also active on the tree at this time. The immediate surrounding habit was low-lying sand dunes with occasional volcanic rocks. In the distance, larger rock formations could be found.

Tarentola hoggarensis – Oued Drâa, ca. 20 km S of Âouïnet-Torkoz, 28°29.00'N, 9°51.17'W, 4 October 2000. This species has a lengthy and involved history of taxonomic revision (Schleich et al. 1996). Due to recent findings within the *Tarentola ephippiata* group, the taxon should be elevated from subspecific status of *Tarentola ephippiata hoggarensis* to full species rank (Böhme et al. 2001; Böhme, pers. comm.). This Oued Drâa specimen (ZFMK 73503) was found by torchlight at night on an *Acacia* tree trunk. This find represents the third discovery of this species in Morocco and is ca. 50 km east of a previously documented locality (Bons and Geniez 1996).

Lacerta andreanszkyi – Imlil, ca. 5 km NE of town, 5 July 1985. The discovery of this specimen (ZFMK 44116) at an alpine meadow at ca. 2400 m elevation confirms its presence in a questionable locality as listed in Bons and Geniez (1996).

Acanthodactylus boskianus – Taroudant, ca. 3 km S of town, 25 May 1985. This species is known to be an inhabitant of dry environments (Bons and Geniez 1996; Schleich et al. 1996). The discovery of this specimen (ZFMK 44079) resting underneath some small bushes marks its first known occurrence in a relatively moist habitat, the Souss River Valley. This report contrasts the findings of Bons and Geniez (1996) whereby they state that *A. boskianus* is absent from the western parts of Morocco, as the Anti Atlas appears to constitute an insurmountable barrier. This finding shows the species to have crossed the Anti Atlas, although the westernmost portion of the Haut Atlas lies due north as a border of this locality. This find is ca. 80 km from the nearest documented locality, though more significantly, it places the species for the first time on the north side of a significantly high mountain range.

Mesalina olivieri – Oued Torkoz – Oued Drâa confluence, 28°29.00'N, 9°51.17'W, 3 October 2000. The discovery of these specimens (ZFMK 73511–512) confirms a suspected locality (Bons and Geniez 1996) in the Oued Drâa. This population is ca. 120 km from the closest confirmed population. Some authors (e.g., Le Berre 1989) regard *Mesalina pasteuri* (Bons 1960) and *olivieri*, both taxa are reported from Southern Morocco (Bons and Geniez 1996),

as conspecific.

Eumeces algieriensis – Tafraoute, 20°43.30'N, 8°58.76'W, 22 September 2000. The diet of this large endemic Mograbin skink consists of invertebrates (Schleich et al. 1996). After hand capture, our specimen regurgitated a gecko which, although partially digested, could be identified as a *Tarentola mauretanica*.

Serpentes

Leptotyphlops macrorhynchus – Amtoudi (Id-Âïssa), 29°13.66'N, 9°13.24'W, 11 June 1985. This specimen (ZFMK 44098) was found in an area lacking vegetation within this oasis village. Though suspected to be a wideranging species in Morocco, secrecy and subterranean habits have surely restricted this species from being routinely encountered and is thus far listed from but ten localities. This discovery in the southern Anti Atlas foothills represents a distance of ca. 80 km from the closest documented record.

Macropodon cucullatus – Plage Blanche, 28°57.73'N, 10°32.89'W, 28 September 2000. According to Bons and Geniez (1996), M. cucullatus is represented by three subspecies in Morocco. The Plage Blanche specimen (ZFMK SA2001:2) keys out to the subspecies *brevis* according to head coloration (Schleich et al. 1996; Wade 1988). Our specimen falls within a ca. 160 km gap between the ranges of the subspecies *cucullatus* and *brevis*.

Bitis arietans – Plage Blanche, 28°57.73'N, 10°32.89'W, 117 m elevation, 28 September 2000. A ca. 90 cm adult female gave birth two days after capture to eight live and two dead neonates. This is a very small litter size as this species is known to commonly have litters of 20–30 with litters of up to 50–60 not being rare (Schleich et al. 1996). *Bitis arietans* from southern Morocco, however, are known to be much smaller in size than their tropical conspecifics.

Echis leucogaster – Oued Torkoz–Oued Drâa confluence, 28°22.00'N, 9°50.00W', 120 m elevation, 19 October 1999. This is one of the rarest of Moroccan snakes (Bons and Geniez 1996), and although known from the Oued Drâa, ours is only the fifth Moroccan specimen (Herrmann and Herrmann 2000). Adult female (SVL 41 cm, TL 44.5 cm) (HLMD RA2888) was found dead, killed by bedouins, and hanging in a bush.

Acknowledgments.—We thank the Philipps University, Marburg, student participants in the 2000 Moroccan Desert Ecology excursion for their participation and companionship. W. Böhme verified some of our species identifications and provided discussion on the taxonomic status of Tarentola hoggarensis. We thank our Moroccan field assistants, especially Blell with his extraordinary knowledge of the herpetofauna of southern Morocco.

St. Louis, Missouri 63103, USA; e-mail: bufalino@slu.edu

Scott and Snyder (1968) reported the plain-bellied watersnake (*Nerodia erythrogaster*) from the lower Cumberland River basin (LCRB) based on specimens they collected from Montgomery Co., Tennessee, USA. This population has been shown as disjunct from the remainder of the species' geographic range (Conant and Collins 1998). Scott and Snyder (1968) described their Montgomery Co., Tennessee specimens as having the copper-bellied watersnake (*N. e. neglecta*) phenotype. Conant and Collins (1998) depict the Montgomery Co., Tennessee population as *N. e. neglecta*, even though they show the yellow-bellied watersnake (*N. e. flavigaster*) occurring further down the LCRB. McCranie (1990) mapped *N. erythrogaster* from this region as *N. e. flavigaster* x *N. e. neglecta* intergrades with a continuous distribution throughout the LCRB terminating in Montgomery Co., Tennessee, near Clarksville.

Our collecting efforts, from August 1996 to June 1999, resulted in several new voucher specimens of *N. erythrogaster* from the area within and around the distributional hiatus shown in the LCRB by Conant and Collins (1998). Cheatham Co., Tennessee, specimen APSU 4316 was collected prior to this work, but is included here to document the easternmost point of this species' distribution in the LCRB. Following are the museum numbers and latitude/longitude coordinates for the new voucher specimens, all of which were verified by David H. Snyder and deposited in Austin Peay State University's Museum of Zoology (APSU). Stewart Co., Tennessee. – APSU 5459 (36°25'48"N, 87°42'05"W), 5462 (36°32'26"N, 87°53'08"W), 5465 (36°24'31"N, 87°36'44"W), 5497 (36°24'40"N, 87°36'16"W), 5498 (36°31'14"N, 87°52'53"W). Montgomery Co., Tennessee. - APSU 5457 (36°23'37"N, 87°17'18"W), 5463 (36°29'23"N, 87°27'20"W), 5481 (offspring of APSU 5463), 5488 (1–8, offspring of APSU 5463), 5491 (1–4, offspring of APSU 5463), 5492–96 (offspring of APSU 5463), 5499 (36°25'42"N, 85°37'12"W), 5977 (36°27'15"N, 87°22'31"W), 6013–14 (36°27'00"N, 87°29'25"W). Cheatham Co., Tennessee. – APSU 4316 (36°17'35"N,

87°05'57"W), 5967 (36°17'28"N, 87°,05'58"W).

Nerodia erythrogaster occurs throughout the LCRB, from Barkley Dam in northern Land Between the Lakes (LBL, Lyon Co., Kentucky) upstream to just below Ashland City, Cheatham Co., Tennessee (Bufalino 1999). The region downstream of Barkley Dam to the confluence of the Cumberland and Ohio Rivers (Smithland, Livingston Co., Kentucky) lacks voucher specimens (Bufalino 1999). *Nerodia erythrogaster* from northern LBL (Lyon Co. and Trigg Co., Kentucky) express an intermediate phenotype, whereas specimens from southern LBL (Stewart Co., Tennessee) upstream throughout the remainder of the LCRB to Ashland City (Cheatham Co., Tennessee), express the *N. e. neglecta* phenotype (Bufalino 1999).

Acknowledgments.—We thank Edward Burchett for allowing us to collect specimens from his property and Jim Wiggington for granting us unrestricted access to Cross Creeks National Wildlife Refuge. Specimens were collected under authorization of the Tennessee Wildlife Resources Agency (permit no. 1112). Austin Peay State University's Center of Excellence in Field Biology supported this research.

Publication of *Distribution of Amphibians and Reptiles in Georgia* (Williamson and Moulis 1994) provided the basis for further study of the county by county distribution of the state's herpetofauna. Additions have been reported, mostly as accounts published in the geographic distribution section of *Herpetological Review*. The majority are from the ongoing Georgia Herp Atlas under the auspices of the Georgia Department of Natural Resources Nongame-Endangered Wildlife Program.

The following new voucher specimens are amphibians and reptiles mostly collected DOR (dead on road) from 1975 to 1999. Photograph vouchers are of live animals that were captured, photographed, and released at the place of capture. Voucher specimens have been verified by Lawrence A. Wilson and are deposited in the collection of the Fernbank Science Center, Atlanta, Georgia. For succinctness and accuracy the sites are reported as longitude and latitude acquired by GPS and/or appropriate U.S. Geological Survey topographical maps.

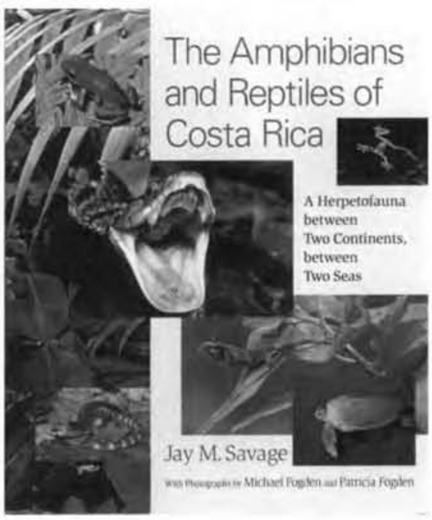
e-mail: lwilson@mdcc.edu

Jay M. Savage, the author of this magnificent and unparalleled book, stepped into Costa Rica in 1960, and, in the ensuing years, became a legend. Now, this legendary figure has produced a fitting culmination to his four-plus decades of research into the composition and distribution of the herpetofauna of Costa Rica.



Savage, now retired and living in San Diego, California, spent most of his career at two institutions, the University of Southern California and the University of Miami. Although his importance to the field of herpetology was apparent before beginning his tenure at USC, it was at this institution and at UM that his full measure was realized. His understanding of the Costa Rican herpetofauna took shape there, of course, but Savage also mentored and sent on their way to distinguished careers a succession of herpetologists, many of whom now hold important positions in the field. The names of some of his intellectual descendents will be familiar to anyone in herpetology: Brian Crother, Maureen Donelley, Ron Heyer, Arnold Kluge, Carl Lieb, Karen Lips, Roy McDiarmid, Norm Scott, David Wake, and Marvalee Wake. Jay Savage was also instrumental in the development and establishment of the Organization of Tropical Studies, which has been hugely influential in education and research in tropical biology. As if this work were not sufficient, Savage has also distinguished himself as a major force in modern biogeography, a talent he again demonstrates in the volume under review (see below).

Costa Rica is world-renowned for its biodiversity, for its government's commitment to protecting that biodiversity, and for its stature as a major ecotourist destination. Its herpetofaunal diversity is no less astounding, and Savage records 390 native species and six introduced ones from the country. This figure includes 172 + 2 amphibians and 218 + 4 reptiles. The area/native species figure for the country is 130.5 (50,900 km^2/390). By comparison, the figure for the much larger Honduras, the centerpiece of my research, is 338.6 (112,088 km^2/331), which is about 2.6 times larger than that for Costa Rica. Costa Rica, thus, possesses an exceedingly rich herpetofauna.

Savage's book will be a rich source of information and analysis for a very long time, not only for professional herpetologists, but for students, resource managers, and ecotourists as well. The broad range of potential users is due to several features of the book not usually seen in treatments of a country's herpetofauna.

The book is organized into four major parts, preceded by a list of keys for identification, a preface, author's acknowledgments, photographers' acknowledgments, and illustration credits. The major parts are also followed by an addendum containing discussion of eight species added to the herpetofauna while the book was in press, a glossary of 831 terms, a literature cited section of 51 pages, a systematic index, and a subject index.

The two-page preface documents Savage's involvement with the Costa Rican herpetofauna. Since 1960, he made more than sixty trips to Costa Rica, which ought to qualify him for honorary citizenship. This experience certainly positions him as the reigning authority on the herpetofauna, which is further evidenced by the number of species with which his name is associated as author. By my count, there are 21 such species, including the famous *Bufo periglenes*, the so-called "golden toad," (a misnomer, according to Savage; the males in this dichromatic species are bright orange, not "golden"), which has become a standard-bearer of amphibian population decline in Mesoamerica. Many of these 21 species were named as a result of broad-based systematic studies undertaken over the years by Savage, for example, on members of the hyper-speciose genus *Eleutherodactylus*.

Part 1, entitled "The Basics," contains three chapters of information introductory to the accounts of taxa. The first chapter (57 pages), "Discovering a Tropical Herpetofauna," is both interesting and peculiar, inasmuch as it contains information not usually seen in treatments of a country's herpetofauna. For example, Savage discusses the basics of systematics, taxonomy, phylogeny, and nomenclature, with especial reference to the cladistic approach. In addition, there is a lengthy discussion of the nature of the conduct of herpetological field research, from locating the animals to captive husbandry of them. This section is followed by two fascinating discussions of the history of Costa Rica and that of the study of its herpetofauna. Costa Rica's history is summarized from pre-Columbian times to the present, the latter characterized by Savage as *la lucha sin fin* (the endless battle). This historical summary assists readers in understanding the cauldron in which the democratic ideal for which Costa Rica is rightly famous was simmered and the stage thus set for the realization of the importance, both scientific and economic, of the immensely valuable biota and its conservation. Savage's summary of herpetological study in Costa Rica is masterful, similarly beginning in pre-Columbian times. This discussion emphasizes the relatively large number of herpetologists who have contributed to our knowledge of Costa Rica's herpetofauna, especially during the twentieth century. We are reminded, for example, of the feud between Emmett R. Dunn and Edward H. Taylor, one chapter of which involved Taylor's entrance into Costa Rica in the wake of Dunn's work there. As Savage recounts the story, Dunn had planned

to write a herpetology of lower Mesoamerica, and had amassed an outline and notes on such a work. This project was delayed, however, when Dunn received a fellowship allowing study in Colombia. Savage speculates that it is during this time that "Taylor was able to copy Dunn's outline and notes for Taylor's subsequent forays into Costa Rican herpetology." Chapter 1 also includes a short section on "Conservation and Protection," including a listing of the many protected areas in the country, which have set the stage for the surge in ecotourism, the country's major economic asset. The chapter concludes with a summary of information sources, species of possible occurrence, and erroneous records, as well as a discussion of the "challenges for readers of this book." It is in this final section of chapter 1 that Savage essentially turns over the reins of responsibility for the study and the protection of the country's herpetofauna to those who will follow him.

Chapter 2 contains a detailed summary (31 pages) of the features of the Costa Rican environment, treating physiography and hydrography, climate, and vegetation and habitats, the last primarily based on the well-known Holdridge system of forest formations.

Chapter 3 (12 pages) deals with the organization of the systematic accounts, which comprise Parts 2 and 3 of this book on the amphibians and reptiles, respectively. The topics covered are the means of identification of these creatures, the use of these sections as an introduction to the biology of the members of the herpetofauna, the purpose of the description of the major systematic groups (family and above) and the genera, the rationale and use of the dichotomous keys, the makeup of the species accounts, the abbreviations used for museums and other collections, and the key to the major groups within the Costa Rican herpetofauna.

The bulk of the book, as expected, consists of the systematic accounts. Part 2 (comprising four chapters) deals with the living amphibians, of which there are 174 species (including two introduced taxa, *Eleutherodactylus johnstonei* and *Osteopilus septentrionalis*). Chapter 4 (eight pages) introduces the class Amphibia, including the living amphibians, members of the subclass Lissamphibia. This chapter also discusses the reproductive modes practiced by Costa Rican amphibians and provides a key to the principal groups of Costa Rican anamniote eggs and developing embryos. Finally, there is a brief discussion of the phenomenon and possible causes of amphibian population decline globally and in Costa Rica. The baffling nature of these declines is alluded to by Savage, who concludes by saying, "It remains open whether anthropogenic stresses are involved and what serious consequences to the health of the global environment may be signaled by declining amphibian populations."

Chapter 5 (eight pages) covers the three genera and four species of caecilians known from the country, all members of the family Caeciliidae. The organization of this chapter is exemplary of the remainder in parts 2 and 3. Initially, the order (here the Gymnophiona) is characterized and the phylogenetic relationships of its components are discussed. Next, the matter of identification is treated and a key to the genera presented. Finally, each of the taxa below the ordinal level are presented and discussed, with identification keys provided at the appropriate points. Each of the species accounts contains the following subsections: diagnostics; description; similar species; habitat; biology; remarks; and distribution (larvae and voice are also discussed in the anuran accounts). In addition, suitably sized distribution ("spot") maps are provided for each species and several line drawings illustrate features of use in identification of taxa.

It is at this point that two of my principal adverse criticisms of Savage's book emerge. First, no synonymies are provided for the species-level taxa that would allow the reader access to the literature on these taxa in Costa Rica. Some of this literature is discussed in the Remarks section of the species accounts, but herpetologists like me who work in another region of Mesoamerica would benefit significantly from such additional knowledge for use in the construction of accounts of species also occurring in such a region. My second major concern is that none of the species accounts contains a list of locality records or specimens examined. From the perspective of one who will make major use of Savage's book in his own research in Honduras, the lack of this information is a serious concern. I understand the interest of editors and publishers (and, perhaps, authors) to contain the size of books of this nature, in order to limit the cost of production and the eventual price of the book, and to not drive off the potential purchasers of the work; however, provision of information on synonymies and available specimens and their localities would save a lot of broadcast searching of the available literature and inquiry to museum curators as to the nature of the holdings of Costa Rican material. This lack also places Savage himself in the position of having to respond to an untold number of inquiries about literature and museum material. In adopting this approach, Savage essentially asks his readers to take his identifications (and the remainder of the information in the species accounts that depends on these identifications) on faith, an approach not terribly popular in the sciences.

Chapter 6 (37 pages) deals with the three genera and 37 species of Costa Rican salamanders, all belonging to the family Plethodontidae. One of these genera, *Bolitoglossa*, is the largest genus of salamanders, with 76 species, according to Savage. The organization of these accounts is like that for the caecilians. It is within this chapter that the first of six sections of color plates is found. This set of 48 plates includes a map of the national parks, biological reserves, wildlife refuges, and other protected areas in Costa Rica, a map of the generalized distribution of Costa Rican vegetation, 16 excellent photographs of vegetation types, six mostly good to excellent photographs of caecilians (not the easiest creatures to photograph), and 24 good to excellent photographs of salamanders. Several line drawings to assist identification are also included.

Chapter 7 (247 pages) covers the anurans, of which there are 133 species in the country, including two introduced species, as noted above. The introductory section preceding the accounts of anuran species is a long one and covers much information on anurans in general and tropical anurans specifically that will be of interest to professionals and non-professionals alike. This information includes discussion of anuran reproductive patterns, ecomorphological tadpole guilds, developmental patterns in anurans based on nutritional sources, keys to adults and larvae, and an index to published illustrations of Costa Rican tadpoles. The 133 Costa Rican anurans are arranged in eight families, about 29% of the 28 families recognized worldwide. These families are the Rhinophrynidae (one species), Bufonidae (14 species), Leptodactylidae (46 species), Hylidae (43 species), Centrolenidae (13 species), Dendrobatidae (eight species), Microhylidae (three

species), and Ranidae (five species). Two sections of color plates are also found within this chapter. The first contains 13 salamander photographs and 79 anuran photographs. The second contains 92 anuran photographs and one lizard photograph. Illustrations of many tadpoles and their mouthparts also accompany this chapter, as well as several of adults indicating diagnostic features and variation in color pattern.

Part 3 (with six chapters) treats the living reptiles, of which there are 222 species (including four introduced forms, *Ctenotus cristatellus*, *Hemidactylus frenatus*, *H. garnotii*, and *Lepidodactylus lugubris*). Chapter 8 is a short (three pages) introduction to the living nonvolant (i.e., non-avian) reptiles, covering diagnostic features and some aspects of biology. Chapter 9 (of two pages) is another short introduction, this time to the squamate reptiles, covering the same subjects as in the preceding chapter.

Chapter 10 deals with the lizards in 121 pages. Seventy-three species are arranged in 22 genera and 11 families (about 39% of the 28 families currently recognized). The families are the Corytophanidae (four species), Iguanidae (three species), Phrynosomatidae (three species), Polychrotidae (27 species), Eublepharidae (one species), Gekkonidae (11 species), Xantusiidae (two species), Scincidae (three species), Teiidae (seven species), Gymnophthalmidae (six species), and Anguidae (seven species). A fourth set of 96 plates is set within this chapter, 94 of lizards and two of snakes. The quality of the photographs in this section ranges from satisfactory to excellent (one shot of a *Norops biporcatus* on a bird of paradise leaf in the forest at the La Selva Biological Station is too small to be of much use, but the understory of the forest is shown to advantage).

Chapter 11 covers the 133 species of Costa Rican snakes in 203 pages. These species are organized into 63 genera and nine families (about 58% of 19 families presently recognized). The families are the Anomalepididae (three species), Typhlopidae (one species), Leptotyphlopidae (one species), Loxocemidae (one species), Boidae (four species), Ungaliophiidae (one species), Colubridae (103 species), Elapidae (five species), and Viperidae (14 species). The final two sets of color plates are located within this chapter. The first set consists of 93 photographs of snakes; the second is of an equal number of the remainder of the snakes, the turtles, and the two crocodilians.

In general, the photographs comprising the color plates are good to excellent in execution, the animals were shot in natural or naturalistic settings, the specimens illustrated are almost all from Costa Rica (by my count, only 29 photographs of a total of 498 are of animals from outside Costa Rica or of unknown provenance), and have good locality data (but no specimen numbers). Most of the photographs were taken by the photographic team of Michael and Patricia Fogden, whose work, it must be acknowledged, will have a lot to do with the popularity this book will enjoy, as Savage himself indicates in the Acknowledgments section.

The 14 Costa Rican turtles are dealt with in Chapter 12 (34 pages) and arranged in nine genera and five families (about 42% of the 12 families currently recognized). The families are Kinosternidae (three species), Dermochelyidae (one species), Cheloniidae (five species), Chelydridae (one species), and Emydidae (four species).

The crocodilians are discussed in Chapter 13 (eight pages). The two crocodilians known from Costa Rica are placed in two genera and a single family, the Crocodylidae (not two families, as indicated in Table 3.1). Savage here regards the Alligatorinae (including *Caiman*) as a subfamily.

Part 4 (with three chapters) examines biogeographic and evolutionary patterns of the Costa Rican herpetofauna. The information and analyses in this final part of the book go significantly beyond those one generally finds in books of this nature and, as such, materially expands the usefulness the book will have to professional herpetologists, especially those working in Latin America.

Chapter 14 is an 11-page discussion of the ecological distribution of the herpetofauna, with about seven of those pages occupied by lengthy tables cataloguing distribution by elevation and forest formations. The raw distributional data found in five tables are summarized in differing ways in three additional tables and four graphs. The analyses point to patterns of distribution that are typically seen in Mesoamerica, for example that salamanders and anurans are most diverse in Premontane Rainforest, most members of the herpetofauna are found in humid lowland forests and Premontane Rainforest, and amphibians are more diverse in the Atlantic lowlands than those of the Pacific.

Chapters 15 and 16 will have broad interest to herpetologists in general and herpetogeographers in particular, inasmuch as they deal with patterns of geographic distribution and evolution of the herpetofauna of Tropical Mesoamerica as a whole, not simply Costa Rica. Savage, of course, has assayed these subjects in earlier papers, especially those published in 1966 and 1983 (see below). Savage justifies treating this subject in such an expansive fashion by indicating that Lower Mesoamerica (principally Costa Rica and Panama) constitutes an isthmian link between the continents to the north and south separating the Caribbean Sea and the Pacific Ocean, which bodies of water were in contact with one another during most of the Cenozoic, noting that "… any attempt to explain the biogeography of amphibians and reptiles in this region must recognize that the Costa Rican herpetofauna is embedded with a broader Tropical Mesoamerican faunal unit" (page 794).

In Chapter 15 (21 pages), Savage places the 215 genera and 42 families of amphibians and reptiles in Tropical Mesoamerica in four major distributional groupings, i.e., widespread tropical (eight genera), South American (62 genera), Tropical Middle American (119 genera), and Extratropical North American (34 genera, of which eight have the southern limit of their range only marginally tropical). Savage also recognizes seven major herpetofaunal assemblages, including an Eastern and Western Lowland Herpetofauna (found in humid regions), a Pacific Lowland Herpetofauna (found in semiarid to subhumid regions), a Mexican Highland Herpetofauna, a Nuclear Highland Herpetofauna (found in Nuclear Middle America), a Talamancan Herpetofauna (highlands of Costa Rica and western Panama), a Panamanian Herpetofauna (subhumid lowland habitats on the Pacific versant), and a Chocoan Herpetofauna (entering eastern Panama in lowland areas). As noted by Savage, Costa Rica is the "meeting ground" of the Eastern and Western Lowland Herpetofauna, the Pacific Lowland Herpetofauna, and the Talamancan Herpetofauna. Savage next identifies the generalized tracks and historical source units evident in tropical Mesoamerica. Four such tracks are identified, familiar to herpetogeographers working in Latin America; they are the North American-Central American track, the South

American-Caribbean track, the Middle American-Caribbean track, and the Western North American-Central American track. Genera and some sub-generic groups whose distributions correspond to a particular track are placed by Savage in a historical unit, of which there are three that have contributed to the Tropical Mesoamerican herpetofauna, i.e., an Old Northern Element (90 genera or subgenera) of largely Laurasian affinities, a South American element (64 genera or subgenera) of Gondwanan relationships, and a Middle American element (66 genera or subgenera), autochthonous in nature. The membership of these elements has been modified substantially from that established earlier by Savage ("1982" 1983), based on current phylogenetic understanding. Savage concludes this chapter with a discussion of nine faunal areas and of endemism within Costa Rica and within the faunal areas recognized. This discussion is used "as the basis for evaluation the history of the Costa Rican herpetofauna" (page 806), which evaluation is presented in the concluding chapter. The nine faunal areas fall into three groupings, viz., lowlands, foothills and uplands, and highlands. Analysis of patterns of distribution within these nine faunal areas and endemism with reference to relative representation of historical elements allows for simplification of the faunal areas recognized to five, whose separate histories are traced in Chapter 16.

Chapter 16 (23 pages) is entitled "Development of the Herpetofauna," and represents a masterful synthesis of paleogeographic, paleoclimatic, biogeographic, and biosystematic data that presents a robust and very satisfying picture of the events that have lead to the composition and distribution of the modern-day herpetofauna of Costa Rica. This type of synthesis is a particular forte of Savage, as he has demonstrated a number of times over his career. As noted above, Savage's approach is a broad-based one, such that his analysis and conclusions will be of significant use to other herpetologists working in Mesoamerica. In approaching this subject, Savage brings together an array of recent geological literature to present the complicated series of geohistorical changes that have shaped the whole of Mesoamerica and especially lower Central America. Thus is the reader introduced to the Maya, Chortis, Chorotega, and Chocó crustal blocks, the Middle American and Colombian trenches, and the five tectonic plates (North American, Caribbean, South American, Cocos, and Nazca) that were the principal players in the geohistory of this region.

Savage next deals with the available paleoclimatic data and the effect paleoclimates had on the evolution of the vegetation in Mesoamerica. Geohistorical and paleoclimatic data are integrated to form a basis for a discussion of the role of dispersal and vicariance in creating the "big picture" concerning faunal assemblages in Mesoamerica. This "big picture," as explained by Savage, has involved the alternation of vicariance (V_0 through V_3) and dispersal (D_1 through D_4) events affecting the historical elements contributing to the modern herpetofauna in complex ways. Of special interest is his exploration of the double-pulse hypothesis of the involvement of the South American Element in the present-day Mesoamerican herpetofauna, especially that of the isthmian region. This hypothesis states that two dispersals of members of the South American Element took place in the Pliocene, at intervals separated by about a million years.

The final section of this chapter provides a satisfying answer for why there are so many species between the two continents and the two seas that bracket Costa Rica. Savage presents this play in five acts. Act one introduced the Mesoamerican Element and the Central American Component of the Old Northern Element to the isthmian island chain when it became sutured to the Chortis block. Act two involved continuing uplift and vulcanism on the emerging isthmus. Act three encompassed the alternating cooling and warming cycles during the latter portion of the Cenozoic. Act four commenced with the reattachment of Central America to South America by the completed isthmian link. Act five involved the dispersal of dry-adapted taxa into northwestern Costa Rica and the Meseta Central. The conclusion of act five brings us to the present, with Savage summarizing the development of the herpetofauna by demonstrating that three historical elements arriving from different directions and at varying times have contributed 97% of the principal players in the herpetofaunal drama that has enjoyed a long run on the Costa Rican stage.

This book is very clean and I have found few errors. However, on page 44, "Stejneger's topological procedures" should read "Stejneger's typological procedures." On page 662, Fig. 11.41 of heads of species of *Leptophis* is placed near accounts of *Drymobius* instead of where it should be, about six pages beyond. The name *Tantilla supracincta* is not italicized in the legend for Plate 457. Finally, the map of the upland areas of tropical Mexico (Fig. 16.9) has a legend placing these areas to the east of the Isthmus of Tehuantepec, instead of west.

I am sure Jay Savage was asked more times than he cares to remember about when this book would see light, but it is abundantly evident that the wait was well worth it. I know of no other herpetological work that purports to cover a country's herpetofauna that is blessed with greater breadth of coverage, attention to detail, freedom from error, quality of illustration, or extent of appeal than is this one, even given my concerns about the absence of synonymies and specimen lists. For those of us who know Jay Savage, we would expect nothing less. This stupendous achievement is only the latest in a long line of distinguished contributions to the field of herpetology from his fertile mind. A copy of this book must be in the library of every person who calls himself a student of herpetology, in every university library, and in the libraries of resource managers and conservationists all over Latin America. Even well educated ecotourists with 75 bucks burning a hole in their pockets will find much of interest in this book, although it is a bit bulky to fit within a daypack. In this day of inflated book prices, this is one book that is definitely worth the monetary outlay. From this point, I can only wait with considerable anticipation to see what comes next from the hand of this talented man.

Preservation of biodiversity requires more than simply establishing preserves and protecting them from human encroachment and direct habitat degradation. Invasive species constitute a very real and present threat to biodiversity of protected areas, and nowhere is this threat more apparent than in southern Florida, where exotic species have profoundly altered the landscape and affected the region's biota.

The impact of invasive species on native forms is often assumed to be negative, but quantitative information on this point is lacking in most cases. Thus, a detailed analysis of the ecology of the Cuban Treefrog—one of the most successful of exotic vertebrates in southern Florida—and of its impact on native species, would be a welcome addition to the literature on invasive species. With this book, based largely on his doctoral dissertation, Walter Meshaka attempts to provide such an analysis. His treatment includes consideration of the geographic distribution of the Cuban Treefrog, its relationship to other members of its genus, and the history of its colonization of Florida. The environment of southern Florida is described with special reference to the Everglades, and a brief chapter outlines the author's methods and the organization of the study. The bulk of the book treats reproduction, larval development and post-metamorphic growth, behavior, habitat selection, stomach contents and diet overlap with potentially competing species, predation, and sexual size dimorphism. The book includes a one and a half page conjecture on the possibility of future geographic expansion of the Cuban Treefrog into other parts of the United States and in the Caribbean, and it concludes with an equally brief chapter on the future of the Cuban Treefrog in the Everglades.

The Cuban Treefrog in Florida is a data-rich volume, the result of the author's energetic and enthusiastic pursuit of his study of this species. He has amassed a large volume of information on this important invasive species. Sadly, the deficiencies in editing, peer review, organization, and production seriously detract from the usefulness of this slim, overpriced volume.

Substantial portions of the book are of little or no relevance to the biology of the Cuban Treefrog, or to its impact as an invasive species. For example, in describing the Everglades the author tabulates the plant communities (Table 3.1) and provides a listing of all species of amphibians and reptiles known to occur in southern Florida (Table 3.2), but this information is not clearly related to treefrog biology.

The manuscript apparently received little, if any, copyediting. How else to explain the numerous run-on sentences, incomplete sentences, awkward constructions, and pronouns with ambiguous antecedents? It is an unusual paragraph that doesn't suffer some grammatical defect. A copy editor would have detected such non-sentences as: "Resting Cuban treefrogs, and especially small individuals, wedged into folds (e.g., palm boots, roof shingles), and large ones often packed into crevices, such as tree cavities or pipes (Meshaka 1996b)" (p. 151). Likewise, a copy editor would never have allowed the following: "Even in all but the most sterile cities that are too developed and antiseptic for its existence, the Cuban Treefrog is a ubiquitous member of the new and as yet unsettled exotic and almost endemic community of the increasingly urban landscape of Florida, itself a barometer of humanity" (p. 177). Surely a copy editor would have noticed that there is much redundancy between some of the tables (e.g., Tables 2.3 and 2.4), or that in many instances the author uses the wrong word or an awkward construction in attempting to convey his meaning, as for example: "One step behind biogeography is origin, both of the genus and the species."

The manuscript cannot have been subject to rigorous peer review, for a knowledgeable reviewer would have pointed out that time should be plotted as a independent variable on the X-axis, not as a dependent variable on the Y-axis, as it is in Figure 1. A reviewer would likely have insisted that the map depicting the distribution of the Cuban Treefrog in Florida (Fig. 1A) have a north arrow, a scale, and an indication of latitude and longitude. A reviewer familiar with the literature of *Osteopilus septentrionalis* would have corrected the author's assertion that "Over the past two hundred years the Cuban treefrog has been a subject of 100 published scientific papers." In fact there have been considerably more than 100 papers published on that species during that time; among others, the author has overlooked Smith and Kohler (1987), Goldberg et al. (1994), and Bartlett and Bartlett (1996). A reviewer familiar with amphibian biology could not have failed to point out that the section entitled "larval growth" (pp. 74–76) actually deals with the duration of the larval period and size at metamorphosis. A reviewer would have advised that it is unnecessary and wasteful of space to illustrate bivariate plots of non-significant regressions (e.g., Figs. 9.3–9.5, 9.11–9.17, 9.20—some with coefficients of determination as low as 0.002!) and that many of the regressions that are reported as statistically significant are of doubtful biological significance, owing to violation of statistical assumptions and/or to the enormous leverage of a few outlying data points (e.g., Figs. 8.2, 8.3).

Overall the production values are poor. In the legends to figures, probabilities are abbreviated as uppercase "P" on some (e.g., Fig. 9.11), or as lower case "p" on others (e.g., Fig. 9.13). F-ratios are reported inconsistently to two, three, or four decimal places. Most figure legends present statistics of dispersion as ±, but in Figures 5.3 and 5.4, they are symbolized as + . Many of the 33 black-and-white photos that illustrate various habitats are repro-

duced too dark (Fig. 4.2C) , are out of focus (Fig. 4.8B), or both (Fig. 4.4B). Many of these photos provide comparison of habitats before and after Hurricane Andrew, but because most are taken from different perspectives, direct comparisons are difficult or impossible (e.g., Fig. 4.12A, B). Many graphs are defective in various ways. Some have different font sizes within a single graph (e.g., Fig. 5.5). Some include regression equations (e.g., Figs. 5.1–5.4), others do not. (e.g., Figs. 5.5, 5.6). Some have broken regression lines (e.g., Fig. 8.5), others have peculiar symbols and lines appearing on them without explanation (e.g., Figs. 8.6, 9.1, 9.24). The axis labels are miss-set on some graphs (e.g., Fig. 8.5), and others have inset labels that overlap, and thus obscure, data points (e.g., Fig. 9.7). The book is severely over-illustrated, with unnecessary graphs and tables that contain much duplicated material. In the scant space of 191 pages, there are 142 figures and tables, an average of one figure or table for every 1.3 pages.

Exacerbating the chaotic writing style are the author's misdirected attempts at humor. In the preface, for example, he sets about framing the study as a mystery in need of solving. A biological crime was committed, he asserts, when an exotic species was "... set loose in a foreign land." The culprit, he would have us believe, was the Cuban Treefrog, and humanity was an accomplice. He then asks rhetorically, "The mystery (my dear Watson) is *why*?" Indeed, as I struggled through this book and reflected on what a properly researched, written, and edited volume on the biology of the Cuban Treefrog could have been, I had the same question.

PUBLICATIONS RECEIVED

New Perspectives on the Origin and Early Evolution of Birds: Proceedings of the International Symposium in Honor of John H. Ostrom, edited by Jacques Gauthier and Lawrence F. Gall. 2001. Peabody Museum of Natural History, Yale University, New Haven, Connecticut 06520-8118. 613 pp. Softcover. US $49.00 + $7.50 postage and handling. ISBN 0-912532-57-2.

This volume includes 31 papers derived from a symposium held at Yale University in February 1999. The symposium itself was linked to an exhibit of feathered theropod dinosaurs from China, but the book deals with broader issues of the phylogeny of theropods, the evolution of birds, the origin of feathers and flight, and the functional morphology and physiology of birds and their ancestors. The contributions range from strictly paleontological to largely neontological and many deal with inferences derived from living archosaurs and other reptiles. Of special interest are a series of papers grouped under the heading "Controversial Topics in Bird Origins." The book is illustrated by 156 black and white photos and line drawings and includes numerous tables and appendices, as well as a comprehensive index. The volume should be a valuable addition to the libraries of ornithologists, paleoherpetologists, vertebrate morphologists, and systematists.

SigmaPlot 2000/2001 for Scientists, by M. Brent Charland. 2002. Riparian House, P.O. Box 721, Merrickville, Ontario K0G 1N0 Canada. 464 pp. Softcover. US $39.95. ISBN 0-9689929-0-0.

This publication serves as a resource for users of the SigmaPlot graphics package and covers the three most recent versions of the software (2000, 2001, and 8.0). It includes information on designing graphs, creating and modifying the graph types supported by SigmaPlot, writing transforms using the built-in programming language, complex curve fitting, and a diversity of other topics. The book is designed with the needs of practicing scientists in mind and aims to maximize the utility of SigmaPlot for both the beginning and advanced user.

Turtles and Tortoises, by Vincenzo Ferri. 2002. Firefly Books, 4 Daybreak Lane, Westport, Connecticut 06880, USA. 255 pp. Softcover. US $24.95. ISBN 1-55209-631-9.

This is an English translation of an Italian book originally published in 1999. It provides an introduction to chelonians and their biology and conservation and provides color photographs of approximately 170 species. More than 150 species are treated in short species accounts consisting of small range maps and text overviewing "Distribution and habitat," "Characteristics," and, in some cases, "Situation" (conservation status). Unlike most such guides, this volume is organized geographically, with major sections on Seas and Oceans and the Palearctic, Afrotropical, Oriental, Nearctic, Neotropical and Australian regions. The book is illustrated by 400 photos of turtles and their habitats and also features partly illustrated keys to the genera of living turtles. A species index is combined with a list of all valid turtle species and, along with a glossary, short bibliography, and list of relevant journals, societies and websites, completes this compact volume. Although aimed at a general audience, the book will also serve as a handy and inexpensive guide to turtles of the world for professional herpetologists.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ukans.edu/~ssar/HRinfo.html#cont>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor or Managing Editor.

Advertising

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR Treasurer (Dr. Theodora Pinou; contact information on inside front cover) or from the SSAR web page (http://www.ukans.edu/~ssar/HRadRates.html).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Donald Schmitt, SSAR Membership Office, P.O. Box 253, Marceline, Missouri 64658, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below) regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

The Thermochron: A Truly Miniature and Inexpensive Temperature-Logger

MICHAEL J. ANGILLETTA JR.
and
AARON R. KROCHMAL
Department of Life Sciences, Indiana State University
Terre Haute, Indiana 47809, USA
e-mail (MJA): m-angilletta@indstate.edu

Miniature temperature-loggers (e.g., HOBO, Watchdog) have become valuable tools for herpetologists, and biologists in general. Being lightweight and self-contained, miniature temperature-loggers make it easy to record simultaneously temperatures at separate sites. Certain models are waterproof and can be attached to or implanted in large organisms, providing detailed profiles of body temperature that are otherwise difficult to obtain (e.g., Butler and Woakes 2001; Litzgus et al. 1999). In some microhabitats, temperature-loggers can even be used to estimate operative environmental temperatures (Vitt and Sartorius 1999). Miniature temperature-loggers are accurate and reliable under field conditions and are generally easier to program and deploy than larger, more expensive systems (Mueller and Rakestraw 1995). Although the use of miniature temperature-loggers has increased rapidly in the last decade, reductions in the size and cost of these devices have not kept pace.

Recently, a novel temperature-logging device has emerged that could enhance studies of behavioral and physiological ecology. The Thermochron iButton, manufactured by Dallas Semiconductors (Dallas, Texas, USA), is a remarkably small and light temperature-logger than meets or exceeds the specifications of temperature-loggers that are commonly used by biologists. Each Thermochron is a mere 5.9 mm thick and 17.4 mm in diameter, and has a mass of 3.1 g. The outer casing is stainless steel, permitting the unit to function normally during complete submersion in water. The Thermochron is powered by an non-replaceable, internal battery that provides approximately 10 years of service (or one million readings). The manufacturer specifies a resolution of 0.5°C and an accuracy of ± 1°C within the operating range of –20° to 85°C. The thermochron was developed primarily as an inexpensive tool for commercial shipping companies to document that perishable goods have been stored and transported within an acceptable range of temperatures. Current pricing is approximately US $14 per unit, and discounts are available for purchases of 25 or more units. Thus, the Thermochron is a high-performance temperature-logger that is approximately 10% of the cost of similar products.

Thermochrons are launched (or "missioned") using free software downloaded from the manufacturer's website and hardware included in a startup kit (US $25). The interface between a computer (Macintosh or PC) and a Thermochron is established with an iButton reader (Blue Dot Receptor, Model DS1402D-DR8), which attaches to a serial port. The software (32-Bit iButton-TMEX Runtime Environment) provides an intuitive interface that allows one to toggle among windows enabling one to mission a logger, display the status of the current mission, and report output from a mission in progress. A mission "wizard" provides an easy to follow, step-by-step process of starting a mission. Advanced features and ranges of settings are almost identical to those offered for competing brands of temperature-loggers (e.g., HOBO Temp loggers used with BoxCar Pro 4.5, Onset Computer Corporation). For example, the output can be obtained in the form of a text file or a histogram of temperatures, and each file is marked with a 48 bit serial number that identifies the logger generating the data. Each mission can record up to 2048 data points, at rates ranging from one point per min to one point per 255 min. The start of the mission can be delayed up to 45 days, so that the user has time to position the Thermochron prior to the onset of data collection.

Thermochrons also possess several unique features. Firstly, the Thermochron can add temperatures to the histogram after the maximum number of time-stamped data points have been stored; therefore, the mean temperature and its variance can be obtained for durations that far exceed the duration of the mission. Secondly, Thermochrons are equipped with an alarm feature that permits monitoring the number and duration of deviations from minimum and maximum temperatures (set by the user). The alarm feature is extremely useful for applications such as monitoring the occurrence of lethal temperatures in nests or hibernacula. Lastly, the Thermochron features 512 bytes of memory that enables the user

to create directories and store the results of a mission. The memory feature of the Thermochron is based on EPROM technology, meaning that data can be accessed even after subsequent missions have been launched and completed.

We obtained 170 Thermochrons (Model DS 1921-F51) to evaluate their performance under laboratory and field conditions. A certified thermometer and a circulating water bath were used to assess the accuracy of Thermochrons over a biologically-relevant range of temperatures (5–50°C). The clock of each Thermochron and a digital watch were synchronized to ensure that our temperature readings from the thermometer corresponded temporally to the temperature readings of the Thermochrons. One hundred Thermochrons were placed in a porous bag and suspended in the water bath with the thermometer. Prior to each temperature recording, the temperature of the water bath was stabilized for ten minutes. On average, Thermochrons deviated 0.3°C from the actual temperature. The magnitude of deviation from actual temperature was fairly consistent across the range of biologically-relevant temperatures (Fig. 1).

To evaluate the effects of prolonged submersion on the performance of Thermochrons, we placed 10 loggers in a water bath at 32°C for a period of one week. Each day we recorded the temperature of the water using a certified thermometer and compared this to the temperatures recorded by the Thermochrons. The average deviation from actual temperature on d 7 (0.3 ± 0.1°C) was not significantly different from that measured on d 1 ($t = 1.24$, df $= 9$, $P > 0.05$). Therefore, prolonged submergence did not affect the operation or accuracy of Thermochrons.

To assess the reliability of Thermochrons under field conditions, 60 Thermochrons were used to monitor soil temperatures in the Pine Barrens of New Jersey. In June of 2001, Thermochrons were buried 6 cm deep at random sites. After 75 days, the loggers were exhumed and data were transferred to a laptop computer. None of the loggers failed during the study, and the data agreed with soil temperatures recorded previously with HOBO data loggers at the same locality (Angilletta et al. 2000).

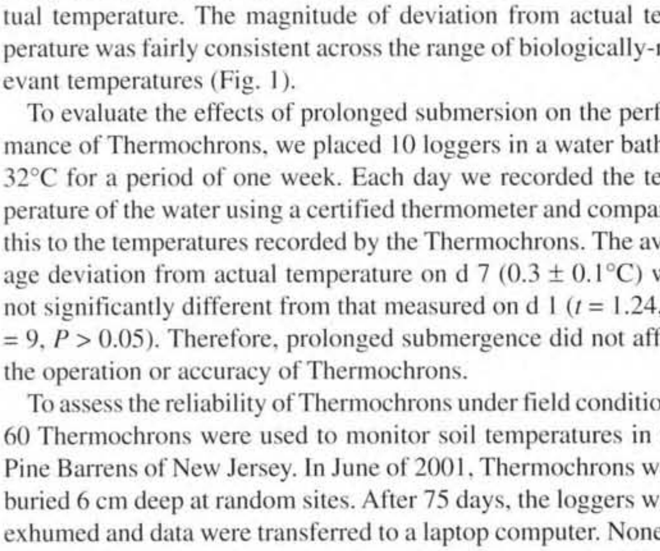

FIG. 1. Over the range of 5 to 50°C, the accuracy of the Thermochron was always better than ± 0.5°C. Accuracy was estimated by calculating the absolute value of the difference between the temperature reported by a Thermochron and the temperature measured with a certified thermometer. Error bars denote 95% confidence intervals.

We found the Thermochron iButton to be an accurate and reliable device for monitoring temperatures in the laboratory and field. Because the Thermochron is much smaller than any other commercially available temperature-logger and can be purchased for a fraction of the cost, they will undoubtedly replace many existing loggers as the model of choice. Their diminutive size and stainless steel exterior enable direct implantation into small organisms (Wang and Adolph 1995), making it possible to monitor the body temperatures of species that could only be studied previously through difficult and time-consuming methods (e.g., cloacal thermometers, radiotelemetry). Their affordable price tag ensures that researchers with modest budgets can benefit from the advantages that Thermochrons provide. More importantly, researchers with ample budgets can ask questions that were logistically impossible to answer in the past. With a reasonable budget, one might afford to thermally "tag" an entire population of individuals. Similarly, environmental monitoring can be carried out at hundreds of random sites in addition to those sites of interest (e.g., nest sites), permitting powerful experimental designs. Based on our experience with the Thermochron, we anticipate that this technology will have a profound impact on the ways in which researchers study the thermal biology of organisms.

Acknowledgments.—We thank Jacques Veilleux for bringing thermochrons to our attention. George Bakken and two anonymous reviewers helped to improve the manuscript.

To study the population ecology of chelonians, researchers have employed numerous trapping methods in different habitats. Pitfall traps, when used in conjugation with drift fences, can be an efficient method to capture terrestrial reptiles (Bury and Corn 1987; Corn and Bury 1990; Gibbons and Semlitsch 1981). Direct methods for capturing turtles include hand collecting with dip nets, snorkeling, and approaching in concealed blinds. Indirect methods include baited hoop nets, fyke nets, snares, basking traps and funnel traps with or without bait (Iverson 1979; Jones 1986; Legler 1960; Vogt 1980; Vogt and Hines 1982). We used capture-recapture methods for estimating the population size of the Indian black pond turtle (*Melanochelys trijuga*), a semi-aquatic species that is terrestrial during the day and forages in water during the night. *Melanochelys trijuga* occurs in the dense tropical rain forests of the Western Ghats in southern India. The forest and terrain of the Western Ghats present unique conditions in which most of the conventional trapping methods do not work satisfactorily.

We tried to capture *M. trijuga* using hoop nets, funnel traps, fyke nets, basking traps and baited pitfall traps. The success rate was generally low for all the devices except baited pitfall traps. Hoop nets and the fyke nets did not work in the shallow and fast flowing streams in our study area, and basking traps were ineffective because these turtles do not bask. Funnel traps did catch some turtles, but the bait got either mixed up or washed off in water. Terrestrial pitfall traps were more effective in catching turtles, especially when used in conjunction with drift fences. However, we encountered problems with non-target animals such as owls, raptors, and otters taking bait from pitfall traps.

To sample this unusual turtle from this imposing habitat, we had to design our own traps. In this paper we describe two traps that were designed to address two of our needs: 1) an aquatic trap that allows thorough sampling of turtles while they are active (floating pitfall trap); and 2) a terrestrial trap in which the bait is protected from non-target animals (see-saw trap).

Floating Pitfall Trap.—We constructed traps from leak-free vegetable oil cans (23 x 23 x 45 cm) made of galvanized iron, which are locally available. The top of the can was cut open and 4-5 kg of stones were added for ballast. "Thermocol" polystyrene sheets (4-cm thick, manufactured by Pidilite Industries Ltd., Mumbai, India) were used to make the boarding platform. A 1 m^2 sheet served as the boarding platform, with a 30 x 30 cm square hole cut in the center (Fig. 1A). The sheet was attached to the top

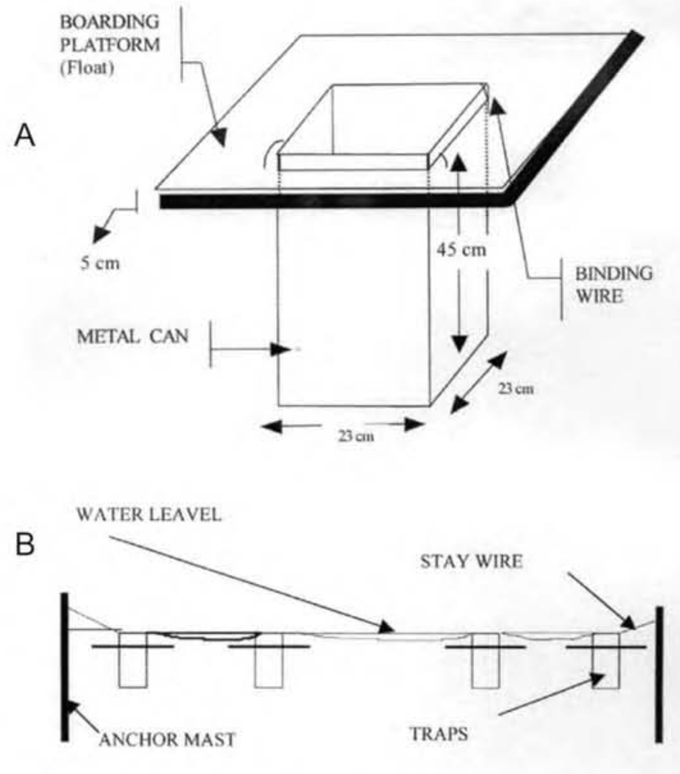

FIG. 1. (A) Front view of the floating pitfall trap. (B) Diagram of floating pitfall traps set in a series.

of the can with thin metal wires in such a manner to allow the can to move freely within the hole. The traps were anchored at a location with stay wires, singly, or several strung together (Fig. 1B). We used chicken viscera to bait the trap. Turtles were attracted by the bait at night, climbed onto the boarding platform, and in an attempt to reach the bait fell into the can. This trap was

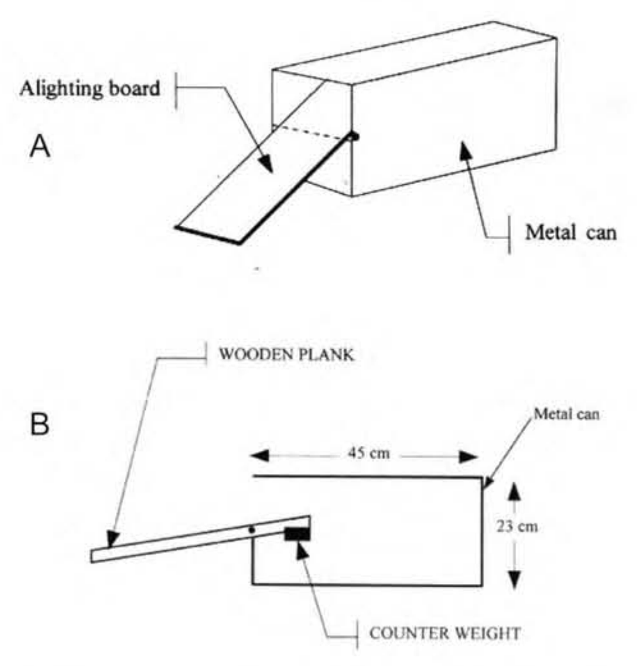

FIG. 2. (A). Diagram of a see-saw trap. (B) Cutaway side view of a see-saw trap.

TABLE 1. Capture efficiency of the two new traps as compared with the conventional pitfall traps.

Trap Type	Bait	Number of traps	Trap nights	Turtles captured	Trapping efficiency
Pit fall	Chicken Viscera	140	8400	452	53.8
	None	5	280	2	7.1
See-Saw	Chicken Viscera	150	4500	416	92.4
	None	5	150	1	6.7
Floating pitfall	Chicken Viscera	25	125	10	80
	None	5	25	0	0

handy for us to capture turtles in shallow and flowing water. It attracted turtles when they were in water but kept the bait dry and exposed so the odor would continue to attract more turtles. However, the trap would sink if there was a puncture in the can, and would get washed away if not anchored properly.

See-Saw Trap.—The same empty oil cans described above with its top cut open was used to make this trap. A wooden see-saw board measuring 45 x 20 cm was inserted through the top so that two-thirds of the board remained outside. A metallic counter weight was attached to inner end of the board (Fig. 2A). The board was loosely hinged to the sides of the can with two galvanized iron nails and was positioned in such a way that it swung freely like a see-saw. The can was then placed on its side so that a turtle could climb into the mouth of the trap (Fig. 2B). As the turtle entered the can, the board dropped, trapping the turtle inside the can. Again we used chicken viscera as bait. This trapping method was especially useful to us as we could trap the turtles when they were on land or were returning to the water. This trap is light and can be set easily, then can be transported to other sites after use. The trap covers the bait and prevents it from being taken away by non-targeted animals. In addition this trap can capture more than one animal at a time.

Laboratory Testing.—First we tested the utility of both these traps in controlled conditions at the Department of Applied Zoology, Mangalore University, Mangalore (Karnataka, India). We used an existing pond measuring 10 x 5 x 3 m where we kept 10 black pond turtles for more than a year. Four see-saw traps were set along the shoreline of the pond and two were set a few meters away. All were baited with chicken viscera, and all remained set for five days. All six traps captured turtles. Later, we set two floating pitfall traps in the tank, also baited with chicken viscera. Both of these traps caught turtles the first night of trapping.

Field Testing.—We field-tested these traps at the Neria field station (12°58'N and 75°26'E), and compared capture rates with capture rates from pitfall traps. The traps were set along the course of two perennial, first order streams, which pass thorough dense tropical rain forests. We analyzed the trapping results of 140 pitfall traps, 150 see-saw traps and 25 floating pitfall traps (Table 1). These traps were baited with chicken viscera. A total of 60 pitfall traps were laid along the banks of hill steams in different habitat types, 40 were laid 10 m away from the stream and another 40 were laid 20 m away from the stream. No drift fences were used in the trials. The see-saw traps were laid randomly along the banks of the stream, but their locations were marked with wooden stakes. The floating pitfall traps were anchored randomly in side pools and deeper regions of the stream. In addition to these baited traps, a smaller set of traps were set without bait (Table 1). All trials were conducted in the dry season only (November to May).

We evaluated the success of the traps by converting the result into the number of turtles trapped per 1000 trap days. The see-saw trap had a capture index of 92.4 and proved to be the most efficient (Table 1). The floating pitfall trap was the second most efficient with an index of 80, and the pitfall trap had an index value of only 51.7 (Table 1).

The two traps described here have since been used successfully, in combination with baited pitfall traps with drift fences made of aluminum, in our efforts to estimate population density of the black pond turtle.

Acknowledgments.—We thank Ullas K. Karanth of Wildlife Conservation Society, New York for technical help and John G. Frazier for motivating the first author. The study was supported by grants from the MacArthur Foundation and the Wildlife Conservation Society. We are grateful to the Hebbar family and the staff of the Neria Estates Pvt. Ltd. for their cooperation in the field.

Testing for Repeatability in Measurements of Length and Mass in *Chthonerpeton indistinctum* (Amphibia: Gymnophiona), Including a Novel Method of Calculating Total Length of Live Caecilians

Individual size remains an important part of any study of reptiles and amphibians, be it systematic or ecological, with countless studies demonstrating the importance of measurements of body length in most taxa (snout to tail tip, snout–vent length, etc., e.g., Lowcock et al. 1992; Scolaro et al. 1985; Vrcibradic and Rocha 1996). However, very few studies have included measurements of live caecilians (Amphibia: Gymnophiona), relying instead on external measurements from museum specimens. For example, Gudynas et al. (1988:16) found that all body measurements were significantly correlated with total length in the semi-aquatic caecilian, *Chthonerpeton indistinctum*: "of 14 significant correlations, eight presented coefficients greater than 0.8." In ecology, size range can be useful in comparisons between populations, and the combination of length and mass is often used to infer the relative condition of individuals over time or between populations.

During ecological fieldwork there is a constant trade-off between collecting as much information as possible, and the reduction of handling time of each individual animal. Ultimately, it is the welfare of the animal that must remain paramount, especially when the normal behavior of the individual is a necessary requirement (such as in mark-recapture experiments). Thus, when an animal is alive, it is not possible to take the ideal full complement of measurements; this makes the precision of measurements that are taken all the more important. Of the numerous publications that include morphometric measurements of live animals, few test to see whether such measurements are repeatable. We believe that testing for repeatability of measurements from live animals should be an integral part of any ecological study that relies on morphometric data.

We consider three conditions important when undertaking measurements from a collection of live animals. Firstly, measurements should be taken by a single operator. Multiple operators tend to have undesired confounding effects on measurements, note taking, and behavior of animals. Secondly, anesthetic should not be used simply to measure an animal. We realize that some procedures require anesthetics (e.g., tagging) and it would seem prudent to take measurements from an animal at such a time. Lastly, we believe that the method chosen should be consistent for future comparison of data. A mixture of data taken with various methods and when animals are under different conditions (e.g., conscious versus unconscious) are likely to be less repeatable.

There are only two principal methods to determine the length of elongate amphibians and reptiles, although we are aware that there are variations on each theme.

1. A fixed rule with calibrated marks to which the animal is straightened, often having to measure the animal in parts as its movements allow. Variations on this theme range from a simple ruler to a rigid calibrated tube through which a live animal is persuaded to move.
2. The string method, in which string is placed along the length of the animal. The length of the string is then retrospectively determined.

The consistent difference between these methods, including all their variants, is that in the first, the measurement apparatus is fixed and, in the second, it is flexible. From a theoretical viewpoint the first method suffers from the problem that animals are not straight and forcibly straightening an animal is bound to lead to errors. Although a tube might seem an ideal way to measure elongate animals, animals tend not lie straight within tubes and in some burrowing taxa (including some caecilians) total length can vary during movement (see Gans et al. 1978; O'Reilly et al. 1997). The string method can also be problematic, especially when measurements need to be taken by a single operator, for example when venomous snakes or slippery caecilians are to be measured.

The magnitude of measurement error in morphometric characters is often surprisingly high (Merilä and Björklund 1995 and references therein). During our fieldwork with the caecilian, *Chthonerpeton indistinctum* (and previous fieldwork by GJM with caecilians, MDB with snakes, and JBS with amphisbaenids) we have experienced considerable difficulty using the aforementioned methods. In particular, we were concerned that measurements using our preferred method—a fixed ruler—were not repeatable. We decided to test this hypothesis by statistical analysis of repeated measures, using the caecilian *Chthonerpeton indistinctum* as a model. We also compare the fixed ruler to another method using the flexible string principle, involving images acquired with a digital camera. At the same time we tested the repeatability of field methods to measure mass, with spring balances and a digital balance.

TABLE 1. Informal terms to describe the measure of repeatability r_i, from Martin and Bateson (1986). Note that these can only be used if results are statistically significant.

R_I	Term
r_i *less than 0.2*	*Slight repeatability*
r_i *between 0.2 and 0.4*	*Low repeatability*
r_i *between 0.4 and 0.7*	*Moderate repeatability*
r_i *between 0.7 and 0.9*	*High repeatability*
r_i *greater that 0.9*	*Very high repeatability*

The semi-aquatic caecilian *Chthonerpeton indistinctum* was collected by excavation during ecological field studies in May 2001 from the Litoral Norte region of Rio Grande do Sul, Brazil. It was necessary to transport 19 specimens from two localities to the laboratory to assess the suitability of marking techniques (see Donnelly et al. 1994; Measey et al. 2001), and it was during this period that the following procedures were made.

To test for repeatability and measurement error in measurements of total length and mass, all 19 animals from both localities were used. Caecilians were temporarily placed within individual containers with a small amount of the substrate in which they were captured. Each container was labeled with a number (1 to 19) and a letter to denote the site of collection. Random numbers were generated using a hand-held calculator to determine the order in which each animal was measured. Animals were treated as if measurements were being taken in the field. Thus, individuals were carefully removed from their containers, cleaned of excess mud (if necessary), placed onto paper towel to remove excess moisture, weighed and then measured before being replaced. Note that were animals to be multiply measured and then replaced, this would constitute pseudoreplication. To avoid potential inter-operator bias, each procedure was carried out by a single operator (1, 2, and 3 by GJM, 4 by JBS):

1. Total live mass was measured using an ACCULAB® Pocket Pro® 250-B (Sartorius Group, Denver, USA), taped with a plastic dish on top of the pan. The animal was placed entirely within the dish and the mass of the stabilized reading recorded.
2. Total length was measured using a fixed plastic ruler with divisions in mm. The animal was placed venter first to the zero end of the ruler. If calmly handled the animal responded by relaxing the posterior body portion, allowing relatively swift measurement of at least two thirds of the body length. The length of this portion was noted on the ruler. The anterior third required some coercion of the animal to lie along the ruler, especially the head and collar region, although minimum manipulation was used to obtain the total length.
3. Two PESOLA® (Pesola, Switzerland) precision spring-balances (10g and 100g) were suspended from a fixed point and zeroed with a length of clear plastic folded to form a sling (ca. 150 x 150 mm, cut from a plastic bag) in which the animal was placed. The measurement of total live mass was then read from the scale.
4. An Olympus C-2100 digital camera was mounted on a tripod 0.5 m from a piece of laminated graph paper. Animals were placed in the center of the graph paper and an exposure made as soon as the caecilian lay in a single plane on the plastic. For most animals the exposure could be made within a couple of seconds as the animal was carefully placed. Occasionally the animal coiled around itself and it was necessary to reposition it before making an exposure. The image was saved as a JPEG file onto a personal computer and was later written to a CD. The image was loaded into Image Tool software (for Windows, Version 2.0). Image Tool is freeware, and the current version can be downloaded from the internet (Wilcox et al. 1997).

   Each image was magnified by a ratio of 1:2 for calibration on a 10 mm section of graph paper. This calibration was then checked by returning the image to 1:1 and measuring 100 mm of graph paper. A result within 1 mm was accepted, otherwise calibration was repeated. A continuous sequence of lines was then drawn over the image in the center of the dorsum of the animal from the snout to tail tip (total length); care was taken to keep the angle between preceding and following lines between 140° and 200° (Fig. 1). The software automatically calculated the total length of the line formed by the sequence of all lines. Image and software distortion is bound to have occurred, although we consider such problems to be insignificant given calibration accuracy.

This process was repeated on all 19 *C. indistinctum* four times, so that each animal was processed five times in total. Records were made without reference to previous measurements. Note that no anesthetic was used, nor were the animals cooled. The whole process took under three hours (excluding time required for analysis of images). The animals were returned to their collection location the following day.

Data were tested for normality using MINITAB. The repeatability of measurements was then tested with one-way analysis of variance (ANOVA, MS EXCEL). Two-tailed paired-sample *t* tests were conducted on averaged data of different methods (MS EXCEL).

The repeatability index or intra-class correlation coefficient (r_i equation 1) can be used to assess precision, i.e., whether an observer makes consistent measurements and whether a trait varies. It cannot be used to measure accuracy of measurements, or differences between observers. Table 1 shows the allocation of classes from the results of repeatability (equation 1). Measurement error (ME) is the percentage of total phenotypic variation in a trait attributable to errors during measurement, calculated on the proportion of within-individual variation to total variation (equations 2 and 3 from Bailey and Barnes 1990).

equation 1 (1 = perfect; 0 = none)

$$r_i = \frac{MS_{between} - MS_{within}}{\left(MS_{between} + (n-1)MS_{within}\right)}$$

equation 2

$$ME = \frac{MS_{within}}{\left(s^2 + MS_{within}\right)} \times 100$$

equation 3

$$s^2 = \frac{\left(MS_{between} - MS_{within}\right)}{n}$$

equation 4

$$AverageDeviation = \sum \frac{\left|\bar{x} - x\right|}{n}$$

Where n is the number of repeated measurements (here five), $MS_{between}$ is the Mean Squares between groups, MS_{within} is the Mean

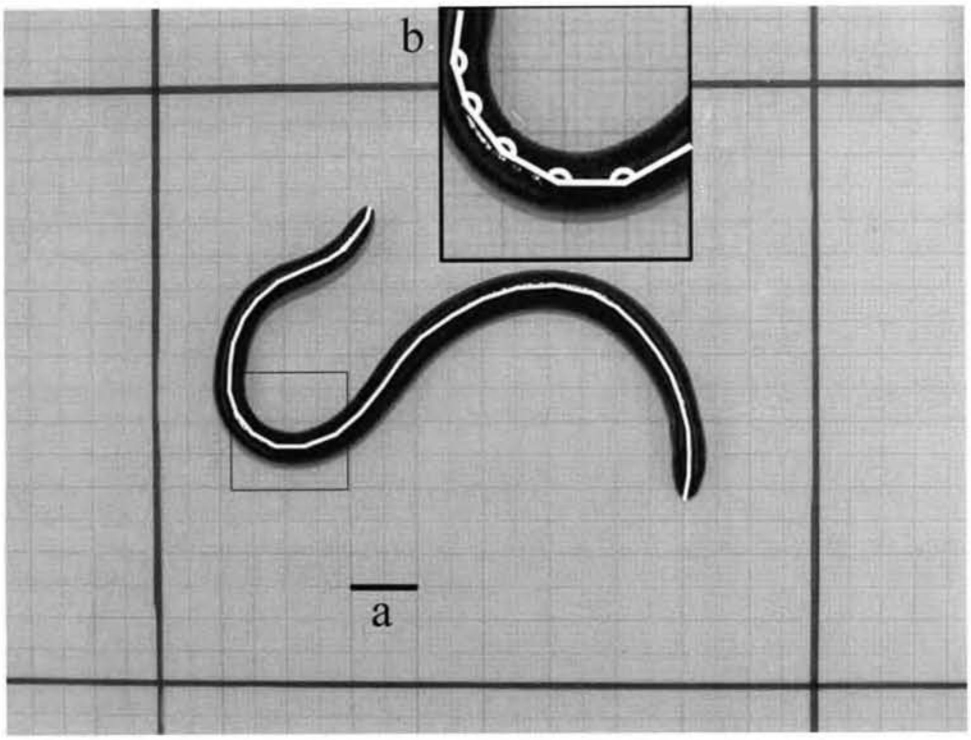

FIG. 1. A typical digital image of a *Chthonerpeton indistictum* juvenile with a sequence of lines drawn along the dorsum. a) 10 mm calibration line and b) inset of increased magnification showing a series of lines with angles (from left to right) of 150°, 163°, 154°, 154°, 166°.

Operation of the camera itself was swift, but more time was spent obtaining length from digital images, approximately 2 minutes for each image. This time involved transfer of data, processing of images with the Image Tool software, and backing up of image files.

The ruler was found to produce significantly longer measurements ($t_{2, 18} = 6.235$, $P < 0.0001$) with an average of 5.7 mm (3.3%). No consistent increase or decrease of length was noted with measurements over time, and differences between trials were not significant (ruler $F_{4, 90} = 0.002411$; $P = 0.999$; camera $F_{4, 90} = 0.008118$; $P = 0.999$).

For valid application of parametric analyses of variance and *t* tests, we must be able to assume that data from each group are obtained randomly from a normal distribution; also that the sampled populations have equal variances (homoscedastic) and have factors with additive levels (Zar 1999). Data in this study were found to deviate significantly from the normal distribution, however we consider that as the sampled populations are essentially the same (being the same animals) this would not invalidate the analysis of variance and *t* tests (see discussion in Zar 1999:185). Data were found to be log-normal, and application of statistical methods to log transformed data did not alter in significance within three decimal places.

Harper (1994) cautions against errors, when making conclusions from repeatability (r_i) calculations, when animals of greatly varying sizes or species are used. In this study two considerably larger adult animals were included, while all others were juveniles (see Fig. 2). It is possible that inclusion of these individuals would

Squares within groups and $\bar{x}$ is the mean of the samples (x).

Measurement of mass.—Both spring balances and pocket balance were easy to use and offered no special difficulties in operation or recording of mass. Operation time of the pocket balance was considerably faster than spring balances resulting in a shorter duration of handling. Fig. 2 shows the mean mass and variation in total length for each method.

Table 2 shows a summary of the data for repeated measures of mass with a very high repeatability for both the electronic and spring balances. Over the five measurements of mass, animals showed consistent loss between first and fifth measurements for the spring balance ($\bar{x} = 0.232$ g) and for the electronic balance ($\bar{x} = 0.159$ g), although this loss was not significant (spring $F_{4, 90} = 0.0021$, $P = 0.999$; electronic $F_{4, 90} = 0.0009$, $P = 0.999$). Weight probably changed as a result of urination, which is common in caecilians when first handling them (GJM, pers. obs.). The *t* test showed significant difference between weights using the two methods ($t_{2, 18} = -2.924$, $P = 0.009$), although the mean difference was smaller than could be measured with these instruments (0.04 g or 0.65%).

Measurement of total length.—Manipulation of individuals for measurement of total length with the ruler was generally easier for larger animals which offered least resistance to being forcibly straightened. Smaller animals often coiled around themselves and were generally harder to work with. Similar behavior was observed when animals were placed on the graph paper under the camera, although the image was usually taken prior to this causing difficulties. Measurement using the ruler was far faster than using the digital camera, but the handling time and severity of handling was far greater with the ruler than when using the camera.

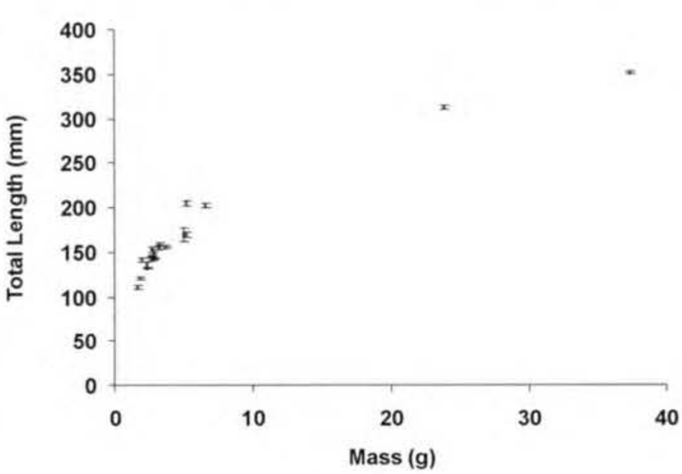

FIG. 2. The distribution of total length and mass of *Chthonerpeton indistinctum* from two localities in Litoral Norte, Rio Grande do Sul, Brazil. Points show the range of length data and averaged mass obtained using a fixed ruler and spring balance (the graph for digital camera and digital balance is visually identical).

produce a bias for the index of repeatability and so the calculations were repeated excluding them (see Table 2).

Precision refers to the closeness to each other of repeated measurements of the same quantity (Zar 1999). All methods presented are precise, showing 'very high repeatability' and an insignificant (i.e., less than 5%) amount of measurement error. This held true (with slightly reduced indices) when only animals of a similar size were measured (by removing the two large animals, Table 2). We do not consider the precision of many operators, as this is known to be considerable (up to 30% in measurements of skulls; Palmeirim 1998); for this reason we suggest that single operators are mandatory.

Accuracy is the nearness of a measurement to the actual value of the variable being measured (Zar 1999). Although it is possible to determine the accuracy of each balance, the accuracy of measurements of total length is somewhat more difficult. The fixed ruler method proved slightly more repeatable, but gave significantly longer measurements, than measurements made from digital images. We suggest that the choice of technique should therefore concentrate on the relative merits of each technique.

The fixed rule is a simple and inexpensive method for measuring the total length of live animals. Equipment is easily obtained, transported, replaced (if broken, stolen, etc.) and can be autoclaved to prevent transport of pathogens; this last point is especially important for herpetologists working with fossorial species (see Halliday 1998). However, we do acknowledge that operation of this equipment requires experience to produce repeatable measurements. Also, data taken with a fixed rule represent a "one off" measurement that cannot be checked by another authority.

The digital camera offers an archive image of each animal enabling measurements to be taken by various operators of the image analysis software. Images can also be used for taking various other measurements (ventral images can be recorded through glass), and other measurements can be obtained retrospectively, given that images are of sufficient quality and have been stored well. Further, images could also be used for identification of individuals (e.g., Donnelly et al. 1994), and charting the occurrence of scars and marks (known to occur in caecilians: e.g., *Scistometopum thomense,* Teodecki et al. 1998; *Gegeneophis ramaswamii,* Measey et al. 2001) on individually marked animals. However, this equipment is presently very expensive and comparatively complicated to use. Moreover, like many electronic products, it is prone to un-repairable error in the field. Time taken to analyze images with the software is significant.

We follow the philosophy of Fellers et al. (1994) who advocate the reduction in handling and handling time. In this study, a general reduction in handling would be made by using an electronic field balance and digital camera to determine the mass and total length of individual *Chthonerpeton indistinctum.* We caution against using the results from this study for other taxa, as behavior of each taxon during measurement might be different. However, we recommend that particularly in studies of growth where measurements are taken from live animals, a method of estimating measurement error is used.

TABLE 2. Results of the multiple measurements on 19 *Chthonerpeton indistinctum* from Rio Grande do Sul, Brazil. Mean Squares, F and Critical value of F were derived from one-way ANOVA (MS Excel). Average deviations calculated from positivized data set. (Figures in parentheses are those from calculations excluding the two adult specimens, N = 17.) † indicates that the same measurement of an animal is producing the maximum or minimum measurement and percentage. * shows the same individual producing maximum and minimum percentages.

Measurement	Mass (electronic)	Mass (spring)	Total Length (ruler)	Total Length (camera)

In the northeastern United States, there are growing concerns about the effects of habitat loss and degradation on vernal pool herpetofauna (Gibbs 1993; Kittredge 1996; Melvin and Roble 1990; Windmiller 1996). Conservation of these species requires effective and efficient methods for surveying their populations. Perhaps the most common method of surveying for adult amphibians involves drift fence arrays in combination with pitfall traps. This method has been used successfully to capture a variety of forest floor vertebrates (Bury and Corn 1987; Gibbons and Semlitsch 1981), including ambystomid salamanders (DeGraaf and Rudis 1990; Madison 1998; McWilliams and Bachmann 1988; Pechmann 1995; Stenhouse 1985; Whiteman et. al. 1994), other salamander species (Gill 1978a,b) and frogs (Guttman et. al. 1991; Yanosky et al. 1997).

Previous studies from around the world have compared the effectiveness of various terrestrial amphibian and reptile trapping techniques. These studies have found varying effectiveness of drift fence/pitfall trap arrays when compared to other methods such as cover boards, pipe traps, visual surveys, box traps and calling surveys (Christiansen and Vandewalle 2000; Crosswhite et al. 1999; Lohoefener and Wolfe 1984; Parris et al. 1999; Sutton et al 1999; Webb 1999). Another method, terrestrial funnel traps, was found to be successful for capturing amphibians along drift fence arrays in the southeastern United States (Enge 1997a). Comparisons of funnel traps to pitfall traps in the Pacific Northwest and the Southwest have shown that snakes and some lizards are more susceptible to capture in funnel traps (Bury and Corn 1987; Jorgensen et al. 1998).

To our knowledge, the only study in the northeastern United States comparing terrestrial trapping techniques for amphibians and reptiles found funnel traps in conjunction with drift fence arrays to be more effective than plastic cover sheets (Kjoss and Litvaitis 2001). A rigorous comparative evaluation of the effectiveness of funnel traps and pitfall traps has not been conducted in the Northeast. Because of rocky soils and wet conditions often found adjacent to amphibian breeding sites in the northeast comparing the effectiveness of terrestrial trapping techniques that can be used in these situations will be valuable.

The goal of this study was to evaluate the effectiveness of terrestrial funnel traps and pitfall traps for capturing amphibians and reptiles by placing the traps along drift fence arrays that encircle

wetlands used by amphibians for breeding. Our specific objectives were to: (1) quantify differences between trap types in capture rates for individual species; (2) quantify community resemblance and differences in species diversity between trap types; and (3) describe mortality rates and logistic constraints associated with each trap type.

We established a drift fence completely around the perimeter of five pools with breeding populations of marbled salamanders (*Ambystoma opacum*) in the town of South Hadley, Massachusetts. Drift fences were installed ca. 2–5 m from the shore (high water) of the pool to intercept all individuals moving to and from the pool. Drift fences consisted of 35 cm aluminum flashing buried 10 cm in the ground and held in place with wooden stakes. We installed pitfall traps and funnel traps alternately every 10 m along each fence for a total of 94 pitfall traps and 102 funnel traps. More funnel traps were used at 4 of the 5 pools because of an odd number of trap sites. A single trap was placed at each location on both sides of the fence. Pitfall traps were made from single #10 tin cans as opposed to double #10 tin cans recommended by Dodd and Scott (1994). We decided to use single cans due to the wet and rocky situations that are often found adjacent to amphibian breeding in the northeast. Each trap contained a wetted sponge and was covered by a board that was leaned against the drift fence to provide shade and prevent desiccation but would not interfere with the capturing of animals. Funnel traps were constructed from aluminum screen by creating a cylinder (41.4 cm long and 18.4 cm diam) and attaching an inverted funnel on either end (Enge 1997b). Like pitfalls, each trap contained a wetted sponge and was covered by a board.

We checked all traps daily between August 20 and November 30 for a total of 103 trap nights per trap. Each trap was checked by removing the sponge and searching through any organic material that may have accumulated in the trap. All animals captured were recorded and released approximately 2 m from the trap on the opposite side of the fence.

To compare the relative effectiveness of each trapping technique, we used a variety of simple descriptive statistics and a series of two-sample t-tests. Specifically, we determined the number and percentage of individuals caught in each trap type across all pools. We used paired t-tests to test the null hypothesis that mean capture rates did not differ between trap types. Here, the pool was the experimental unit. Mean capture rates for each technique were paired by pool to account for differences in overall capture rates among pools. In effect, this tested the null hypothesis that the mean difference in capture rates between techniques did not differ from zero (i.e., zero difference in mean capture rates between techniques exists when the relative capture rates between the two techniques is the same at each pool, regardless of differences in the absolute magnitude of capture rates among pools). For this analysis, capture rates for each species were calculated at all five pools by dividing the number of animals captured in a given trap type by the number of traps of that type. This step was necessary to account for minor differences in the number of traps of each type at a pool.

To compare the relative effectiveness of each trapping technique at estimating amphibian and reptile diversity, we computed Simpson's diversity index (Simpson 1949) for each trap type at each pool. Simpson's diversity index is calculated as the proportion of each individual species' abundance relative to the total abundance of all species squared. The squared proportions for all species are then summed, and the reciprocal is taken. We tested the null hypothesis that diversity did not differ between trap types using a paired t-test, as described above. In addition, we compared the community structure as determined by each technique using two different community resemblance measures. Specifically, we computed Jaccard's Coefficient of Community Similarity (Mueller-Dombois and Ellenberg 1974:212–214) to assess similarity in species composition. Jaccard's index is defined as the number of species common to both trap types divided by the total number of species found in both trap types, and is zero when two communities have no species in common and is a maximum of one when two communities share all species. We also computed percentage of similarity (Wolda 1981) to assess similarity in community composition and structure between trap types. Percentage of similarity is defined as the sum of each species' lowest percent composition from either trap type. Percent similarity is zero when two communities have no species in common and is a maximum of one when species composition and relative abundances are identical. For this analysis, we computed community resemblance for each pool separately and then summarized these results across all five pools.

Collectively, a greater number of species (15 vs. 10) and more individual amphibians and reptiles (1622 vs. 764) were caught in funnel traps than in pitfall traps (Table 1). Based on total number of captures 14 of 15 species were captured more frequently in funnel traps than in pitfall traps. However, when we only looked at species with > 20 captures, eight species had higher capture rates with funnel traps compared to only one species with pitfall traps. Despite these results, because of high variability among pools, capture rates were significantly different at the $P < 0.1$ level for only three species (*Ambystoma opacum*, *Plethodon cinereus*, and *Rana sylvatica*) and at the $P < 0.05$ level for only one species (*Rana sylvatica*) based on paired t-tests. The only species to have significantly greater capture rates in pitfall traps was the marbled salamander (*Ambystoma opacum*).

Funnel traps consistently captured a higher diversity of species across the five pools (Fig. 1), although this difference was only mildly significant ($t = 2.36$, $P = 0.077$). The similarity in community composition between trap types was low (mean Jaccard's Coefficient of Community Similarity = 0.54). Similarity in community structure (i.e., composition and relative abundances) was

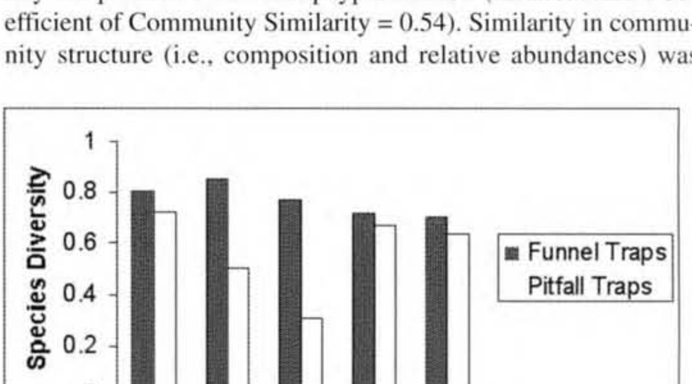

FIG. 1. Reptile and amphibian diversity captured in each trap type (funnel and pitfall) in Fall 1999 at 5 pools in South Hadley, Massachusetts.

TABLE 1. The number and percentage of captures in funnel (N = 102) versus pitfall (N = 94) traps, mean deviation in capture rates between trap types, and P-values from paired t-tests for individual species captured along drift fences around five vernal pools in South Hadley, MA during 1998. Deviations between trap types were computed for each pool separately and then averaged across pools. Positive deviations represent higher funnel trap capture rates; negative deviations represent higher pitfall trap capture rates. Mean deviations between trap types and associated P-values are only reported for species with greater than 20 total captures.

Species	Total Captures				Mean	
	Funnel Traps		Pitfall Traps		Deviation	P-value
Rana sylvatica	273	(93%)	19	(7%)	5.007	0.001

slightly greater, but also low (mean Percentage of Similarity = 0.61).

Overall, mortality rates were low (< 2% of captures) and were similar between trap types, although there were notable differences among species (Table 2). Funnel traps accounted for higher amphibian mortality rates, primarily because animals captured in them were more susceptible to desiccation. Two species seemed especially prone to desiccation in funnel traps, *Notophthalmus viridescens* and *Plethodon cinereus*. Ambystomid species appeared to be less susceptible to desiccation, yet suffered greater mortality in pitfall traps due to predation by shrews. In addition, pitfall traps accounted for more small mammal mortalities, most likely due to high metabolic rates of carnivorous shrews (Churchfield 1990).

TABLE 2. Total number of mortalities associated with funnel traps and pitfall traps for species captured along drift fences around five vernal pools in South Hadley, Massachusetts during 1999.

Species	Funnel Trap	Pitfall Trap
Ambystoma maculatum	0	1
Ambystoma opacum	1	3
Eurycea bislineata	0	1
Hemidactylium scutatum	1	0
Notophthalmus viridescens	7	2
Plethodon cinereus	6	1
Rana sylvatica	3	0
Total Amphibians	18	8
Small Mammals	1	16
Total Mortalities	19	24

From a practical and logistical standpoint, both trap types required roughly an equal amount of initial labor (i.e., construction and installation), but funnel traps required more time to check and maintain and were more expensive to construct. In particular, funnel traps required resetting after they were checked. Resetting involved placing the trap tightly against the fence and the ground so that no gaps existed where animals might circumvent the trap. This proved not to be a problem in relatively wet areas, but in dry uplands, it took approximately 30 sec longer to reset a pair of funnel traps properly than to reset a pair of pitfall traps. Hence, with over 100 funnel traps to check in our study, funnel traps required almost an additional one hour of labor per day.

Clearly, species' capture rates and estimates of community composition and structure can differ markedly when different trap types are used in combination with drift fence arrays (Bury and Corn 1987; Lohoefener and Wolfe 1984). No one trap type is equally effective for capturing all species. However, pitfall traps are often employed as the only trap type in amphibian surveys. In our study, funnel traps were more successful for capturing most amphibians and reptiles and sampling a greater diversity of species than pitfall traps, with the exception of marbled salamanders. The differential vulnerability to trap types among species can be explained by the physical structure of the two trap types in relation to species' physical capabilities. In our study, we used relatively shallow pitfalls

(one #10 tin can) compared to recommended pitfall depths (two #10 tin cans) (Dodd and Scott 1994) because shallow, rocky soils prevented us from installing deep pitfalls at all sites. Thus, in order to maintain constant trapping effectiveness among sites, we were limited to the use of relatively shallow pitfalls. Preliminary work suggested that shallow pitfalls were sufficient for capturing our target species, the marbled salamander. The shallow pitfalls allowed snakes and frogs to readily escape, yet were quite effective for ambystomid salamanders. Conversely, funnel traps were quite effective for snakes, frogs, and some salamanders because they function as confusion traps that make it difficult for animals to find their way out. Our results indicate that funnel traps provide a viable and potentially more effective alternative to traditional pitfall traps when used in combination with drift fences, especially in situations that prevent the use of pitfalls altogether (e.g., wet areas) or prohibit the use of deep pitfalls (e.g., in shallow and rocky soils).

Acknowledgments.—We thank Al Richmond, Scott Jackson, Scott Melvin, Richard DeGraaf, and Bob Brooks for advice and guidance. We thank Mark Grgurovic, Dan Wong, Miranda Buck, Suzie Fowle, Silvia Schmidt, and Leeanne Siart, for help in the field. We thank Ryan Baum and Jeremy Shive for editorial comments on the manuscript. Gen Ed Power Co. provided funding for the project, and the Massachusetts Division of Fisheries and Wildlife handled negotiations.

Heloderma horridum (Beaded Lizard) and *H. suspectum* (Gila Monster) are the only extant species of venomous lizards. Because of this, they are popular animals in both public and private reptile collections and are subjects of considerable herpetological interest. Although their venom is rarely fatal to human beings, helodermatid bites can be extremely painful and can have systemic effects, including a rapid drop in blood pressure, which can result in hypotensive shock (Burnett et al. 1985, Preston 1988). Bites are surprisingly common, but often go unreported in the literature (Lowe et al. 1986). Thus, extreme caution should be used when handling these lizards. Although there are many published techniques for handling venomous snakes (e.g., Mauldin and Engeman 1999; Murphy 1971), little attention has been given to venomous lizards.

At times, helodermatids may be handled by mechanical means (hooks and tongs) although these tools can be cumbersome and possibly cause injury to the lizard. Therefore, manual handling may be necessary. Often, zoo workers don heavy leather gloves in the belief that this minimizes the likelihood of being envenomated. We are aware of individuals who have been bitten through leather welding gloves, not only by *H. suspectum,* but by small viperids as well. These gloves create a false sense of security. Other workers are confident that one can handle these lizards by the ends of their tails, believing that the lizards are not flexible enough to allow mouth contact with the hand holding the tail. We have had experiences (without being bitten) that negate this belief. Though slow in movement, helodermatids are surprisingly quick to strike (especially laterally) at objects that approach their heads. Additionally, they can contort their bodies in a U-shape that places the mouth adjacent to the tail. Therefore, it is foolhardy to attempt to grasp these animals unless the head is also restrained.

FIG. 1. Placement of locking hemostat during restraint of a small *Heloderma horridum.*

FIG. 2. Placement of hand behind hemostat during restraint.

We have used the following technique for several years, which we believe adds to the safety of workers attempting manual restraint of helodermatids. We use a common 18–24 inch (46–61 cm) locking hemostat as a flared yoke that compresses the neck of the lizard to the substrate, virtually eliminating the lizard's ability to move the head laterally, and positions a protective barrier between the grasping hand and the lizard's head. Initially, the hemostat is placed over the neck of the lizard just behind the posterior margin of the jaw (Fig. 1). Once the animal is restrained in this manner, one can safely grasp the lizard behind the hemostat (Fig. 2), remove the hemostat while maintaining a firm grip around the neck of the lizard, and then use the free hand to raise and support the lizard's body (well away from its head). To release the animal, reverse the process and end with both hands clear of the animal before removing the hemostat from around the lizard's neck. The ratcheting lock of this type of hemostat allows one to adjust the yoke width to accommodate most lizards of different head sizes.

NATURAL HISTORY NOTES

The Natural History Notes section is analogous to Geographic Distribution. Preferred notes should 1) focus on observations with little human intrusion; 2) represent more than the isolated documentation of developmental aberrations; and 3) possess a natural history perspective. Individual notes should, with few exceptions, concern only one species, and authors are requested to choose a keyword or short phrase which best describes the nature of their note (e.g., Reproduction, Morphology, Habitat, etc.). Use of figures to illustrate any data is encouraged, but should replace words rather than embellish them. The section's intent is to convey information rather than demonstrate prose. Articles submitted to this section will be reviewed and edited prior to acceptance.

Electronic submission of manuscripts is requested (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Authors without the ability to send manuscripts electronically may supply hard copy instead. Figures can be submitted electronically as JPG files, although higher resolution TIFF or BMP files will be requested for publication. If figures cannot be provided in this format, you may send them to the section editor for scanning. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ukans.edu/~ssar/HRinfo.html. Manuscripts should be sent to the appropriate section editor: **Marc P. Hayes** (amphisbaenids, crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; cpainter@state.nm.us); **Gordon W. Schuett** (snakes; Gschuett@zooatlanta.org); and **James Harding** (turtles; hardingj@pilot.msu.edu).

Standard format for this section is as follows: SCIENTIFIC NAME, COMMON NAME (for the United States and Canada as it appears in Crother [2000. *Scientific and Standard English Names of Amphibians and Reptiles of North America North of Mexico, with Comments Regarding Confidence in Our Understanding*. Herpetol. Circ. 29:1–82]; for Mexico as it appears in Liner [1994, *Scientific and Common Names for the Amphibians and Reptiles of Mexico in English and Spanish*, Herpetol. Circ. 23:1–113]), KEYWORD. DATA on the animal. Place of deposition or intended deposition of specimen(s), and catalog number(s). Then skip a line and close with SUBMITTED BY (give name and address in full—spell out state names—no abbreviations). (NCN) should be used for common name where none is recognized. References may be briefly cited in text (refer to this issue for citation format).

Recommended citation for notes appearing in this section is: Lemos-Espinal, J., and R. E. Ballinger. 1994. *Rhyacosiredon leorae*. Size. Herpetol. Rev. 25:22.

CAUDATA

AMBYSTOMA CALIFORNIENSE (California Tiger Salamander). **PREDATION.** *Rana catesbeiana* was introduced into California in the late 1800s (Jennings and Hayes 1985. Herpetol. 41:94–103). *Rana catesbeiana* is a generalist predator, known to consume a wide variety of prey (Bury and Whelan 1984. Ecology and Management of the Bullfrog. USDI Fish & Wildlife Service Res. Publ. 155. 23 pp.). Until now, published documentation of predation on *Ambystoma californiense* (a species petitioned for federal listing as threatened) by *R. catesbeiana* has been lacking.

We removed bullfrogs from a private stockpond near Rancho Murietta, Sacramento County, California, USA (38°25'09"N, 121°03'19"W) on three separate occasions between March and June 2000. Bullfrogs were collected by hand, net, or gig and then euthanized. We dissected and preserved all stomachs in the field and later identified stomach contents to order (for invertebrates) or species (for vertebrates). Most stomachs contained arthropods; primarily adult and larval beetles (Coleoptera) (66%) and clam shrimp (Conchostraca) (20%). One larval *A. californiense* was recovered from the stomach of a male *R. catesbeiana* (150 mm SVL, 346 g). The salamander, ca. 9.5 cm in total length, had been recently ingested and was easily identified (now deposited at California Academy of Sciences; CAS 222659).

Our report corroborates an unpublished observation by Anderson (1968. The Reproductive and Developmental History of the California Tiger Salamander. Unpubl. Master's thesis. Fresno State College. 82 pp.), who found one larval *A. californiense* in the stomach of a 79 mm SVL bullfrog taken in early April 1968 from a temporary pond on the eastern side of the San Joaquin Valley in Madera County.

STITT**, University of Arizona, School of Renewable Natural Resources, 125 Biological Sciences East, Tucson, Arizona 85712, USA (e-mail: estitt@u.arizona).

AMBYSTOMA MACULATUM (Spotted Salamander). **VERNAL MIGRATION.** Immigration of ambystomatid salamanders to breeding ponds may be triggered by changes in temperature and rainfall, and may be affected by endogenous circannual and circadian clocks. Blanchard (1930. Am. Nat. 64:154–167) concluded that immigration in *A. maculatum* is initiated by the first rains following snowmelt and ground surface thaw. Hillis (1977. Bull. Maryland Herpetol. Soc. 13:84–91) and others also stressed the importance of rainfall as an effector of immigration. Sexton et al. (1990. Copeia 1990:781–787), however, concluded that 3-day average temperature (mean of daily high, low temperatures) is the most useful predictor of *A. maculatum* immigration, though all immigration in that study was associated with rainfall. Sexton et al. (*op. cit.*) also concluded that the lack of immigration during December and January despite favorable conditions of temperature and rainfall represented a refractory period perhaps based upon an endogenous circannual clock.

We report here very early immigrations of *Ambystoma maculatum* in central Virginia (USA). The first occurred on 7 January 1998 in northern Albemarle County, Virginia; this was the first observed migration of the 1997–1998 season. The immigration was observed as *A. maculatum* crossed State Road 643 to reach ephemeral ponds in the floodplain of the South Fork of the Rivanna River. A total of 20 individuals (15 live, 5 dead) were observed; all were male. Other species observed at the same time and location were *Bufo sp.* and *Pseudacris crucifer*. The sightings occurred between 2145 and 2330 h during rain. Temperature and precipitation preceding this migration were as follows (low temp., high temp., total daily precipitation, respectively): 5 January: 2.8°C, 18.9°C, 0 cm; 6 January: 12.8°C, 20.0°C, 0.41 cm; 7 January: 16.1°C, 20.0°C, 1.1cm (mean 3-day temperature 15.1°C). Mean 3-day temperature recorded at the Charlottesville 2 W station (13 km south of observation site) for these dates from 1948 to 1995 was 2.0°C. There was no measurable rainfall two days prior to observed activity, but 0.41 cm and 1.1 cm of rainfall were recorded the day before and the day of immigration, respectively.

The next noted migration was observed in rain around 2140 h on 11 February 1998; 9 *A. maculatum* (7 live, 2 dead) were observed, 8 of which were male. Temperature and precipitation preceding this migration were as follows (low temp., high temp., total daily precipitation, respectively): 9 February: -2.8°C, 11.7°C, 0 cm; 10 February: -1.7°C, 15.6°C, 0 cm; 11 February: 0.0°C, 8.9°C, 1.4 cm (mean 3-day temperature 5.3°C). Mean 3-day temperature recorded at the Charlottesville 2 W station for these dates from 1948 to1995 was 1.7°C. There was no measurable rainfall

for the two days prior to observed activity, but 1.4 cm rainfall was recorded the day of immigration.

This report represents the earliest documented observation of vernal immigration of *A. maculatum* at this latitude. Our observations support previous general conclusions that increased temperature and nocturnal rainfall influence immigration of ambystomatid salamanders to vernal breeding ponds (Hillis, *op. cit.*; Douglas 1979. Can. J. Zool. 57:2303–2310; Sexton et al., *op. cit.*), and that male *A. maculatum* immigrate before females (Hillis, *op. cit.*; Douglas, *op. cit.*). They also concur with Sexton et al.'s (*op. cit.*) model of immigration induction by a minimum 3-day average temperature of approximately 5.5°C in conjunction with 0.127 cm minimum rainfall the day of immigration. However, these observations are at odds with Sexton et al.'s (*op. cit.*) hypothesis that a clock-derived refractory period prevents immigration during December/January (in St. Louis Co., Missouri).

Submitted by **MICHAEL S. GRACE**, Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901, USA (e-mail: mgrace@fit.edu), and **DON R. CHURCH**, Department of Biology, University of Virginia, Charlottesville, Virginia 22903, USA.

DICAMPTODON COPEI (Cope's Giant Salamander). **COLORATION**. On 7 August 2001, one of us (LLCJ) collected a partial albino *D. copei* in a tributary of Iron Creek in Skamania County, Washington, USA (T10N R7E SE 1/4 W 1/8 Sec. 8). It was found under a 15 x 4 cm rock on gravel in a small riffle just below Forest Road 25. The larval specimen (University of Washington Burke Museum; UWBM 2310) was 44.1 mm SVL, 72.8 mm TL, and 2.9 g. Water temperature was 12°C and air temperature was 23°C at the time of capture, 1402 h. A normally pigmented *D. tenebrosus* of about the same size was found < 2 cm from this specimen. Both species are common in the stream. This specimen was identified as *D. copei* based on the presence of discrete dorsal patches lacking dermal and epidermal melanophores. This is the first record of an albinistic specimen for this species (Dyrkacz 1981. SSAR Herpetol. Circ. 11). The specimen is essentially leucistic, based on criteria of Dyrkacz (*op cit.*). The only pigmentation on the head, body, and tail consisted of scattered epidermal black melanophores on the dorsal and lateral surfaces, giving the salamander a light gray appearance. Melanophores were most concentrated along the base and tip of the tail. The venter lacked pigmentation and appeared translucent. The specimen had melanic eyes with some coppery chromatophores above the pupil. The most conspicuous feature was the lack of dense, brown dermal melanophores typical of the species. The specimen was kept in captivity for a few weeks, but did not exhibit marked color changes that might be attributable to the influence of environmental factors (Fernandez and Bagnara 1991. Gen. Comp. Endocrinol. 83:132–141). Three partial albino *D. tenebrosus* larvae reported by Nussbaum (1976. Misc. Publ. Zool. Univ. Michigan 149:1–94) had a similar description: they had reduced dorsal pigmentation and black eyes, but no specific mention of coppery ocular chromatophores was made.

We thank Philip Fernandez for advice and Marc Hayes for review of the manuscript.

ENSATINA ESCHSCHOLTZII OREGONENSIS (Oregon Ensatina). **COLONIZATION**. *Ensatina eschscholtzii oregonensis* is one of the most common terrestrial salamanders in managed (Aubry 2000. J. Wildl. Mgmt. 64:1041–1052; Butts and McComb 2000. J. Wildl. Mgmt. 64:95–104; Grialou et al. 2000. J. Wildl. Mgmt. 64:105–113) and unmanaged (Aubry and Hall 1991. *In* Ruggiero et al. [tech. coord.], Wildlife and Vegetation of Unmanaged Douglas-fir Forests, pp. 236–338. U.S. Forest Service, Gen. Tech. Rep. PNW-285; Bury et al. 1991. *In* Ruggiero et al., *op. cit.*, pp. 341–350) forested landscapes in the Pacific Northwest. Despite a general notion of abundance, knowledge of its movement ecology, and thus, colonizing potential, is largely unknown. Hence, we present data from a human-altered landscape in western Washington (USA) that provide preliminary information on this species' colonization ability.

The site is in rural Thurston County northwest of Olympia, 3.2 km S of the end of the Cooper Point Peninsula between Budd and Eld Inlets on the south end of Puget Sound (47°06'59.7"N, 122°56'09.4"W). At 36 m elev., habitat consists of a successionally varied mosaic of Douglas-fir (*Pseudotsuga menziesii*)-western hemlock (*Tsuga heterophylla*) forest (Franklin 1988. *In* Barbour and Billings [eds.], North American Terrestrial Vegetation, pp. 104–130. Cambridge University Press, New York). The focal area is a 0.33-ha unit with its long axis (~130 m) bordering 59th Avenue, a single-lane (4 m wide) paved road with a 1.5-m open shoulder on each side. Most of the unit has 60–100 year old Douglas-fir, but the east quarter, which abuts a 0.6-km gully draining to Eld Inlet, is vegetated with red alder (*Alnus rubra*) and big leaf maple (*Acer macrophyllum*). The area to the immediate north (i.e., along 59th Avenue) is a > 5 ha Douglas-fir forest of similar age, whereas areas to the immediate west, south, and east are variously developed with single-dwellings on large (≥ 0.5 ha), but heavily manicured parcels, or horse pastures. Soil is a high clay fraction, highly compacted glacial till (USDA Soil Conservation Service 1990. Soil Survey of Thurston County).

In January 2001, all trees except one 120-cm DBH Douglas-fir were removed from the middle third of the focal unit, and an understory (mostly English holly [*Ilex opaca*] and Himalayan blackberry [*Rubus discolor*]) was removed from 90% of that area. Thus, except for the trees left standing on the east and west thirds, most of the unit had a relatively uniform exposed compacted clay surface during 2001. On 17 July 2001, 6.1 m^3 gravel-to-small boulder-sized basaltic rock was deposited on this barren surface over a 12-m^2 area at 2 m S of 59th Avenue near the unit mid-point. Between late July and October 2001, hand removal of rocks reduced the volume of this pile about two-thirds with the remnant covering 4 m^2. During removal, the substrate and rocks were dry, and no *E. e. oregonensis* were noted. On 19 February 2002, during preparation to move the remaining pile with a tractor, we found a juvenile (40 mm SVL) *E. e. oregonensis* after turning only a few rocks. To avoid injury to other salamanders potentially present,

we systematically dismantled the rest of the pile by hand prior to tractoring it. This search revealed 11 additional *E. e. oregonensis.* All were concentrated in a 1 m^2 area that had been the least disturbed, had the best developed interstitial spaces (interstitial spacing in much of the pile was limited because mud and crushed rock filled spaces among rocks), and was nearest the road. Of 12 salamanders found, 9 were smaller (SVL: mean = 39.4 mm, range: 34.0–45.0 mm; mass: mean = 1.7 g, range: 1.2–2.3 g) and could not be confidently sexed. The other three were larger (SVL: mean = 53.5 mm, range: 51.0–56.0 mm; mass: mean = 3.5 g, range: 2.6–4.8 g) and were sexed based on development of cirri, oviducts, or eggs (the latter two by candlelighting). Two of the larger individuals were females. The largest (56 mm SVL, 4.8 g mass) was a female carrying at least 6 eggs, each ca. 3 mm in diameter.

Salamanders had to move at least 10 m to reach the rock pile (closest occupied habitat is 10 m N across 59th Avenue). If movements were from other directions, distances moved may have been considerably greater than 10 m; Staub et al. (*op. cit.*) cautioned against long-term sampling of *Ensatina* with small plots precisely because of the frequency of movements > 10 m. Most colonizing individuals were juveniles and the remainder appeared to be young adults, suggesting that young individuals may be the more frequent colonizers. Colonization likely occurred after September 2001. *Ensatina* are known to move following fall rains (Stebbins, *op. cit.*), so we expect that colonization of the pile occurred after 11–15 October, when the first soaking fall rains occurred in 2001. Our observations emphasize that colonization of proximate novel habitat can occur within four months within the same season, given environmental and seasonal conditions appropriate for movement. Because we do not know the precise date of colonization, potential exists for colonization to occur in a few days of novel habitat creation depending on its timing. Lastly, it emphasizes that human alteration of such habitat may require awareness that colonization may have occurred in order to avoid placing salamanders at risk.

Submitted by **MARC P. HAYES**, Habitat Program, Washington Department of Fish and Wildlife, 600 Capitol Way North, Olympia, Washington 98501, USA (e-mail: mhayesrana@aol.com), and **CHARLEEN B. HAYES**, 2636 59th Avenue NW, Olympia, Washington 98502 USA.

NOTOPHTHALMUS VIRIDESCENS LOUISIANENSIS (Central Newt). **BRANCHIATE ADULT**. The life cycle of *Notophthalmus viridescens* has been described previously by many authors, but only a few branchiate adults (those possessing retained gills) have been reported. We collected 17 *N. viridescens louisianensis* from a small partly wooded, man-made pond on 26 January 2002. This pond was located ca. 0.4 km east of Taylor Road, Randolph Co., Arkansas (T20N R3W Sec 4). Upon examination we discovered one branchiate adult that appeared in every other respect to be an adult male/female aquatic form. The individual possessed external gills, gill slits, and free opercular folds. This observation appears to be the first recorded instance of this morphology from Arkansas (Trauth, Plummer, and Robison. ms. in prep.). The locality where this individual was collected has been subjected to a multi-year drought that undoubtedly spanned the lives of the branchiate individual, its parents, and possibly the grandparents. The pond is permanent and fishless. These combined attributes may have induced the expression of branchiate phenotypes within this Ozark population, since this morphotype had not been discovered during previous visits to the site.

PLETHODON CINEREUS (Eastern Red-backed Salamander). **CANNIBALISM**. For many species of Plethodontidae, the risk of cannibalism of juveniles by adults is believed to be an important force affecting their socioecology (Camp and Lee 1996. Copeia 1996:78–84; Jaeger and Forester 1993. Herpetologica 49:163–175; Jaeger et al. 1995. Ecology 76:533–543). However, unlike more aquatic salamanders with long larval periods (e.g., *Ambystoma* spp.), evidence of cannibalism for more terrestrial species is rare. Adult cannibalism of juvenile *P. cinereus* has been reported in staged laboratory encounters (Bachmann 1984. Herpetologica 40:436–443; Wareing 1997. Honor's Thesis, State Univ. New York at Binghamton, Binghamton, New York), but a review of numerous studies summarizing the diets of thousands of *P. cinereus* has failed to find a single case of adult cannibalism of a juvenile, and one of us (JCM) has sampled the diets of several thousand adult *P. cinereus* from numerous sites, in all seasons, and under a variety of conditions, and never documented a single event of cannibalism (Maerz, unpubl. data).

On 9 May 2001, within 24 h of rain, we conducted a routine survey of artificial coverboards at a long-term mark-recapture study site in Syracuse, New York, USA. During the survey we collected diet samples from 52 *P. cinereus* by stomach flushing (*sensu* Fraser 1976. Ecology 57:459–471). We recovered a juvenile *P. cinereus* from the stomach of an adult male *P. cinereus*. The juvenile was a striped morph 11 mm in length between the fore and hind limbs (could not determine SVL because of state of digestion). The juvenile's size indicates it was a young-of-year hatched in August 2000. The head of the juvenile was almost completely digested, the forelimbs were partially digested with all the skin gone, and posterior of the mid-trunk was slightly digested with most of the skin intact and stripe clearly visible. This suggests the juvenile was swallowed headfirst. The juvenile's tail was detached and well digested, suggesting the male may have attacked toward the tail first, the tail autotomized and was consumed, and then the male attacked the juvenile a second time. The male that consumed the juvenile was a lead morph, 39 mm SVL, reproductively active, and a recurring resident under the coverboard. On the day we recovered the cannibalized juvenile from the male, we also found another *P. cinereus* young-of-year and a juvenile *P. cinereus* 35 mm SVL under the same coverboard. In addition to the juvenile *P. cinereus*, the male's stomach contained a centipede (1.46 x 0.67 mm), an isopod (1.83 x 1.28 mm), a small dipteran (1.55 x 1.01 mm), and part of an earthworm (4.66 x 0.94). The number and volume of prey in the male's diet was normal to above average

(Maerz 2000. Ph.D. Diss., State Univ. New York at Binghamton, Binghamton, New York). Based on the amount of other prey in the male's stomach and that the sample was collected within 24 h of rain when access to prey is generally not limited for *P. cinereus* (Jaeger 1980. Oecologia 44:335–341; Maerz 2000, *op. cit.*), it is unlikely that the male was food-limited at the time he cannibalized the juvenile.

Our observation of adult cannibalism of a juvenile in a wild *P. cinereus* population is the first such observation that we are aware of. Because the diets of *P. cinereus* have been studied extensively, it is unlikely that the rarity of cases of cannibalism in wild populations is the result of limited observation. Rather, it is likely that behaviors reduce the real occurrence of cannibalism in the wild. Adult *P. cinereus* can identify and avoid cannibalizing their own offspring (probably chemically) (Jaeger et al. 1995, *op. cit.*; Waering 1997, *op. cit.*; Wareing 1998. Master's Thesis, State Univ. New York at Binghamton, Binghamton, New York), and some juvenile *P. cinereus* can use chemical cues to avoid unrelated adults and their territories (Wareing 1997, *op. cit.*; Forester and Anders 2000. *In* Bruce et al. [eds.], The Biology of Plethodontid Salamanders, pp. 407–416, Kluwer Acad./Plenum Pubs., New York, New York; though see Wareing 1998, *op. cit.*). Our observation shows that cannibalism does occur in wild *P. cinereus* populations, and when considered in the context of laboratory studies, supports the inference that cannibalism is an important force shaping *P. cinereus* social behaviors.

SIREN INTERMEDIA NETTINGI (Western Lesser Siren). **PREDATION**. Natural predators of *Siren intermedia* remain largely undocumented (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 587 pp.), but are known to include mink (*Mustela vison*) and great egret (*Casmerodius albus*) (Frese and Britzke 2001. Herpetol. Rev. 32:99). The following observations, made from the margins of a bald cypress swamp at Lake Martin, St. Martin Parish, Louisiana, USA, represent two previously undocumented predators of *S. intermedia*.

On 30 November 2001 at 0900 h, RCD observed a great blue heron (*Ardea herodias*) standing in shallow (< 50 cm) water, killing and consuming a *S. intermedia*. From a standing position, the heron captured the siren with its bill from at or beneath the surface of the water. For ca. 3 min, the heron bit down on the siren's neck and repeatedly moved the siren back-and-forth through its bill, rapidly biting the entire length of the salamander, including the anterior portion of the tail. The heron then consumed the siren in a single action, by swallowing it headfirst. Based on the size of the heron, the *S. intermedia* was judged to be 30–35 cm TL. This observation was made with 8 x 30 binoculars from a distance of ca. 25 m.

On 15 December 2001 at 0830 h, we observed a red-shouldered hawk (*Buteo lineatus*) carrying a *S. intermedia* in its talons (in flight) to a horizontal bald cypress branch 12–14 m above the surface of shallow water, where it landed and began consuming the salamander. Initially chased by another red-shouldered hawk, the hawk possessing the siren did not interact with any other birds while perched. On its perch, the hawk held the siren's body between its talons and the branch, with the siren's tail dangling over the branch. After perching motionless for 2–3 min, the hawk began tearing, with its bill, and consuming flesh from the neck and head of the siren. Because we did not observe the actual predation event, we are unable to state exactly how the hawk acquired the siren. Based on the size of the hawk, the *S. intermedia* was estimated to be 30–35 cm TL. This observation was made with a 40x spotting scope from a distance of ca. 30 m.

Although neither *S. intermedia* observed could be collected, both were identified based on the presence of conspicuous reddish external gills and a clear absence of rear legs (front legs were visible on both individuals). Both of these characteristics eliminate the only sympatric and superficially similar animal, *Amphiuma tridactylum*. The size of both specimens (30–35 cm TL) is also consistent with the 18–69 cm TL range of *S. intermedia*, and well below the 46–106 cm TL range of *A. tridactylum* (Petranka 1998, *op. cit.*).

ANURA

ADENOMERA* cf. *ANDREAE (NCN). **VOCALIZATION**. The importance of advertisement calls in species recognition and as pre-mating isolating mechanisms in most species of anurans has long been recognized (Blair 1964. Quart. Rev. Biol. 39[4]:334–344; Blair 1974. Amer. Zool. 14:1119–1125). The distinctiveness and species-specificity of these calls allow workers to identify individual species under field conditions, making them particularly useful in discriminating among cryptic species. Such is the case in the Neotropical leptodactylid genus *Adenomera*, which has typically been a systematically difficult group given the overall similarity among member species. Heyer (1984. Amphibia-Reptilia 5:97–100) suggested that topotypic advertisement call data could help resolve *Adenomera* systematics, and current research involving vocalizations indicates there are cryptic species within some of the more widespread nominal species in the Amazon Basin and southeastern Brazil (Angulo, Cocroft, and Reichle, *in press*, Herpetologica; Boistel, de Massary, and Angulo, *in press*, Amphibia-Reptilia; Kwet and Angulo, *in press*, Alytes).

Adenomera andreae and *A. hylaedactyla* are the two nominal species known to occur over a wide area of sympatry in the Amazon Basin, with *A. diptyx* at the southernmost border of the Basin (I. De la Riva, pers. comm.). Audio recordings of individuals from a population in Campamento Segakiato, on the margins of Rio Camisea, province of La Convención, department of Cusco, southeastern Peru (11°48'23"S, 72°52'51"W, 380 m elev.), have been compared to the call data available for populations elsewhere in the Amazon Basin. Herein we report on a new vocalization for Amazonian *Adenomera*, represented by one vouchered individual (Museo de Historia Natural de San Marcos, Lima, Peru; MHNSM 18219) and three unvouchered recordings (N = 4 frogs).

The vouchered male was calling with other conspecifics, on the forest floor, close to a stream, at an air temperature of 27°C. Of the three unvouchered males, two were recorded at 27°C and one at

TABLE 1. Summary of acoustic parameters of the new vocalization for *Adenomera* cf. *Andreae* (N = 4 frogs; 30 calls per frog, N = 120 calls).

	Call length (ms)	Call rise time (ms)	Call rate (calls/min)	Dominant frequency (DF) (Hz)	Secondary frequencies (Hz)		Change in DF (Hz)
Mean	29	6.44	60.5	2370.06	4682.59	7118.85	558.6
SD	4.09	4.06	13.14	76.57	110.27	114.31	163.74
Range	21.2–37.7	1.6–14.8	30–78	2247.7–2466.5	4475.6–4873.4	6663.7–7304.6	1203.1

26°C. Recordings were obtained on 12 October 1997 between 1730 and 1750 h, using a Sony Walkman Professional WM-D6C tape recorder and AKG D 1200E microphone. Signals were analyzed using Signalyze 3.12, a Macintosh-based program, sampling at a rate of 44100 Hz and 16 bytes resolution. Acoustic parameters measured and their corresponding values are in Table 1. The definition of all parameters, with the exception of secondary frequencies (frequency bands other than the carrier that contain significant energy), and change in dominant frequency, follows Cocroft and Ryan (1995. Anim. Behav. 49:283–303). Change in dominant frequency is defined as dominant frequency at the end of the signal minus dominant frequency at the beginning of the signal.

The vocalization has a mean duration of 29 ms, occurring at a relatively low call rate (ca. 60.5 calls/min). Two individuals consistently presented a call "trail" (Fig. 1b) which follows the main signal in either a sustained or interrupted fashion, but as the other callers did not have this feature, call measurements were done on the main signal. The duration of the main signal plus the trail is highly variable (40–97 ms). The fundamental frequency is at the same time the dominant frequency, with an upward frequency glide of about 500 Hz.

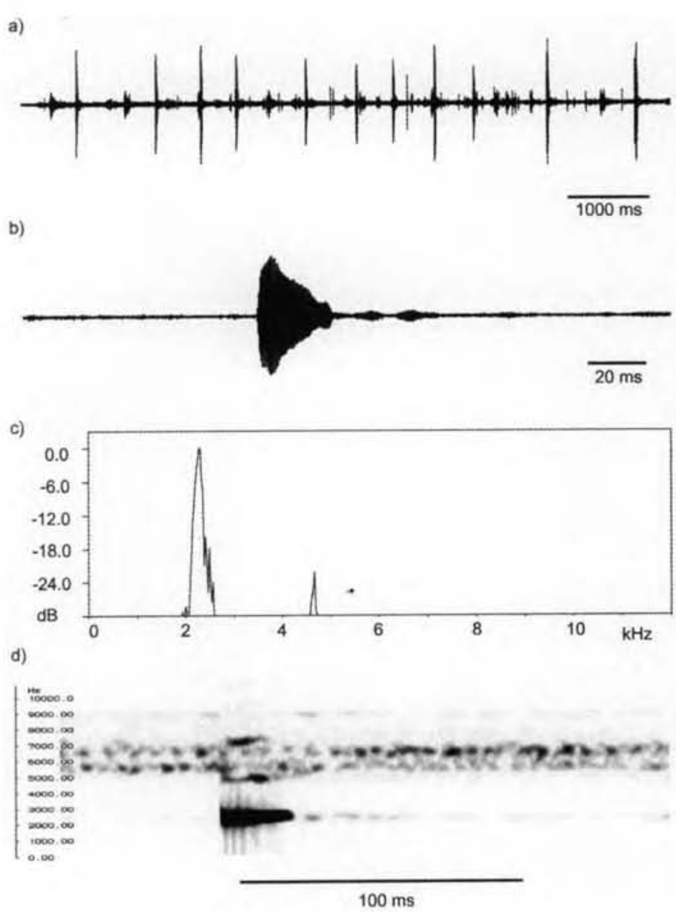

FIG. 1. a) Oscillogram of several calls and b) waveform, c) power spectrum and d) spectrogram of a single call.

In an attempt to determine the identities of these individuals we examined acoustic parameters of Amazonian *Adenomera* from calls reported in the literature. We also compared our results with recordings of a sympatric *A. hylaedactyla* and recordings elsewhere in the Basin (Angulo, Cocroft, and Reichle, unpubl. data.). The new vocalization differs from unpublished recordings and from those previously reported by having a dominant frequency that is at the same time the fundamental frequency, while in all other cases (*A. andreae, A. hylaedactyla*, and *A. diptyx*) the main carrier is the second harmonic. The new call type is notably shorter than that of *A. andreae* (Zimmerman and Bogart 1984. Acta Amaz. 14:473–519), *A. diptyx* (as *A. andreae* in Márquez et al. 1995. J. Zool. Lond. 237:313–336 [I. De la Riva, pers. comm.]), and *A. hylaedactyla* (Heyer 1973. Contr. Sci. Nat. Hist. Mus. Los. Angeles Co. 251:1–50; Straughan and Heyer 1976. Pap. Avulsos Zool. 23:221–245; Schluter 1980. Salamandra 16[4]:227–247; Schneider et al. 1988. Zool. Jb. Physiol. 92:77–103; Márquez et al. 1995, *op. cit.*).

Considering its short call length and peculiar spectral energy distribution, and given that it occurs in sympatry with *A. hylaedactyla* and at least one other *Adenomera*, this vocalization is sufficiently different from any other known Amazonian *Adenomera* call to presume it to represent a distinct but cryptic species. Given that the group is currently the subject of systematic studies and that the taxonomy may change, we have called this population *Adenomera* cf. *andreae* as the specimen shares some characters with nominal *Adenomera andreae* and occurs in forested habitats.

We thank the Man and Biosphere Program, Smithsonian Institution, and the Shell Oil Company for logistic support, INRENA (Instituto Nacional de Recursos Naturales) for granting appropriate permits, Departamento de Herpetología, Museo de Historia Natural de San Marcos, for use of its facilities, and G. K Morris for reviewing the manuscript. Support is acknowledged from operating NSERC grant #4946 to G. K. Morris.

AGALYCHNIS CALLIDRYAS (Red-eyed Treefrog). **REPRODUCTION.** This species usually deposits eggs on vegetation overhanging temporary and permanent ponds (Duellman. 2001. The Hylid Frogs of Middle America. SSAR Contrib. Herpetol. 18:i–xvi, 1–694, i–x, 695–1159). McCranie and Wilson (2002. The Amphibians of Honduras SSAR Contrib. Herpetol. 19:i–x, 1–625), in addition to these usual breeding sites in Honduras, reported finding an amplectant pair on passion flower vines growing above a trickle of water coming from a pig pen, amplectant pairs in primary rainforest where the only other nearby surface water seen was that in streams and a river and a tree buttress, tadpoles in small water-filled depressions made by human and pack animal traffic along a trail (these depressions lacked overhanging vegetation where eggs are normally laid), tadpoles in a small stationary side pool of a stream in the dry season, egg clutches attached to the rubber walls of a water collecting device with tadpoles in the stagnant water of this device, and eggs attached to the walls below the seat in a latrine (although it is highly unlikely that tadpoles from this egg clutch could survive). Some of these unusual breeding sites were in heavily deforested areas.

On 5 August 2001 in primary lowland rainforest (60 m elev.) at Caño Awawás (14°49'N, 84°52'W), Gracias a Dios, Honduras, at ca. 1200 h, we located a fallen tree with a long cavity of water. Upon examining the log, we found several clutches of greenish colored *Agalychnis* eggs attached to leaves of vines and small trees overhanging the water-filled cavity and *Agalychnis* tadpoles in the water. One egg clutch (USNM 549422) and one lot of tadpoles (USNM 549423) were collected at that time. We returned to the site at dusk (ca. 1600 h) on the same day and waited for dark. The distinctive call of *A. callidryas* was heard in the trees above the log. After dark (ca. 1700 h) we examined the log and saw several *A. callidryas* around the log and in vegetation above the log. We collected two adults (USNM 549331–32) and made another collection of *Agalychnis* tadpoles (USNM 549424). Examination of these two tadpole lots (stages 25–37; Gosner 1960. Herpetologica 16:183–190) confirmed that they were *A. callidryas* tadpoles. Observations over the years in Honduras have revealed that *A. callidryas*, with its specialized mode of reproduction (normally laying eggs on vegetation overhanging temporary and permanent ponds), has surprisingly adapted to breeding in a wide array of habitats. This ability to adapt has allowed the species to remain common in some places even after its primary rainforest habitats are completely deforested.

BUFO FOWLERI (Fowler's Toad) and ***MALACLEMYS TERRAPIN TERRAPIN*** (Northern Diamond-backed Terrapin). **REFUGIA AND NESTING.** In the context of a nesting and hatchling study of *Malaclemys terrapin* during Summer 2000 and 2001 in Bayville New York, we recorded multiple observations of the use of terrapin nest excavations by *Bufo fowleri*. Our study site is a 1-ha, flat, sandy plot adjacent to an estuarine marsh of Oyster Bay, on the north shore of Long Island.

In our study site, female terrapins frequently begin an excavation and abandon it before it is complete, moving several meters to another location. Such excavations, typically 5–10 cm deep, which we have termed "test holes," are common in our study site. Once the female completes an acceptable nest it is cylindrical, ca. 11–20 cm deep, and the egg chamber usually measures 4–10 cm in diameter (Montevecchi and Burger 1975. Amer. Midl. Nat. 94:166–178). In our study site, when the hatchlings emerge from the nest they often leave a conspicuous oval-shaped emergence hole, which is ca. 3–5 cm across at the surface and extends ca. 4–12 cm deep (Bossert and Draud, unpubl. data). Approximately 25% of the terrapin nests were predated by raccoons in our study site. This predatory action left a hole that was slightly larger in diameter than, and as deep as, the original egg chamber.

During September 2000 we examined 58 emergence holes and found *Bufo fowleri* residing in 3 (5.2%). During June 2001 we examined 28 test holes and found 2 *B. fowleri* (7.1%). In addition, we examined 20 raccoon-predated terrapin nests, and found 1 toad (5%). During September 2001, we examined 63 emergence holes and recorded 5 more resident toads (7.9%). Thus, over the two-season period, 6.5% of the 169 terrapin excavations examined had toads residing in them. Over the same two-season period, seven other toad observations were recorded in the study site (e.g., under various objects or hopping along the ground).

The Fowler's toads found residing in terrapin excavations ranged from 42–63 mm SVL. It is unknown if all 11 occasions were different toads, but from the locations, times, and sizes we believe that they were. In each case, a solitary toad was buried in the soft sandy soil at the bottom of the nest, head facing up. Our data do not allow us to comment specifically on the length of time the toads spent within the terrapin excavations, but in 2001, 2 of the 8 observed toads remained in the same excavation for at least 3 days. Since nest density is high in our study site (mean density = 2.22 nests /100 m^2), it is entirely possible that they would use several different excavations within their home range, which has been conservatively reported to range between 100 and 1000 m^2 (Clarke 1974. Amer. Midl. Nat. 92:257–274).

Bufo species use various naturally occurring depressions for water conservation, crypsis, and thermoregulation, and *B. fowleri* have been reported to use small mammal burrows (Clarke 1974, *op.cit.*), but to our knowledge this is the first published report of their use of turtle excavations. Fowler's toads are thought to dig into loose sand to hibernate and typically are not active at the surface after late September in our study area. Given our discovery of toads buried in terrapin excavations in late September (latest observations was 25 Sept) we believe it is likely that in addition to using the excavations as refugia, they may also use them for hibernacula. Fowler's toads have also been observed in empty terrapin nests in Wellfleet, Massachusetts (Don Lewis, pers. comm.). It is unknown how widespread the use of empty turtle nests by Fowler's toads might be, but we speculate that wherever large populations of toads coincide with active turtle nesting areas, it is likely to be a common occurrence.

CYCLORAMPHUS BORACEIENSIS (Flattened Waterfall Frog). **CLUTCH ATTENDANCE**. The 25 known species of *Cycloramphus* occur in the coastal Atlantic Forest. Information on reproduction is scarce and is restricted to two species. In both, the eggs are laid outside the water, are large, and are attended by the female (Heyer and Crombie 1979. J. Washington Acad. Sci. 69:17–20) or by the male (Giaretta and Cardoso 1995. Revta Bras. Zool. 12:233–237). On 2 January 2001 (1200 h), at the Cachoeira do Ipiranguinha, (Ubatuba, SP, Brazil; 23°26'S; 45°04'W), we found a clutch of *C. boraceiensis* eggs in a rock crevice near a waterfall. Close (30 cm) to this clutch we found a male hidden under a dead leaf. This male was collected, examined for natural marks, and released at the point of collection. We returned to the site during the night (2030 h) and found that the previously discovered male was sitting beside the clutch (Fig. 1). This male (AAG-UFU 2309, Museu de Biodiversidade do Cerrado, Universidade Federal de Uberlândia) measured 40.9 mm SVL. The clutch contained 43 eggs, and the embryos (10 mm TL) were at stage 22 (Gosner 1960. Herpetologica 16:183–190). Another association between a male *C. boraceiensis* (36.8 mm SVL) and an egg clutch (58 eggs, stage 17 embryos) was observed at the same waterfall on 28 December 1989. This male was in a situation similar to that illustrated in Fig. 1, during the day (0800 h). Male *C. dubius* remain close to their eggs and repel approaching objects. The presence of males of *C. boraceiensis* beside the clutch is suggestive of paternal care in this species, as in *C. dubius*.

FIG. 1. Adult male *Cycloramphus boraceiensis* close to a clutch of eggs in a rock crevice. Note that the eggs are in contact with one another and in a single layer; note also the late stage embryos inside the eggs.

Submitted by **ARIOVALDO A. GIARETTA** and **KÁTIA G. FACURE**, Laboratório de Sistemática e Ecologia de Anuros Neotropicais, Instituto de Biologia, Universidade Federal de Uberlândia, 38400-902, Uberlândia, Minas Gerais, Brazil.

CYCLORAMPHUS BORACEIENSIS (Flattened Waterfall Frog). **DEFENSIVE BEHAVIOR.** The leptodactylid *Cycloramphus boraceiensis* is restricted to the coastal Atlantic Forest of Brazil (Heyer et al. 1990. Arq. Zool. 31[4]:231–410). During field work between January 2000 and April 2002 at Núcleo Picinguaba (44°50'W; 23°23'S, 10–50 m elev.), Parque Estadual da Serra do Mar, in the municipality of Ubatuba, State of São Paulo, Brazil, we observed bite defensive behavior in *C. boraceiensis*. When disturbed, individuals of this species usually remained motionless with limbs close to the body (death feigning). Although, on 6 occasions we observed individuals biting the hand of one of us when they were hand-captured. This species inhabits wet rock surfaces in forest streams, and due to its concealing coloration the primary defense was crypsis; secondary defense was thanatosis (death feigning) and biting. Bite behavior for the genus *Cycloramphus* was described for *C. dubius* by Giaretta and Cardoso (1995. Revta. Bras. Zool. 12[2]:229–232), and was considered parental care behavior, because individuals were found near clutches. In the present report we have not observed clutches near the individuals of *C. boraceiensis*. One individual of *C. boraceiensis* captured a frog (*Hylodes phyllodes*) used as bait, and another individual was observed preying on a tadpole of *Thoropa miliaris* which inhabits humid rock surfaces. These episodes suggest that *C. boraceiensis* is a voracious predator that may use this biting behavior as a defensive mechanism. Among defensive behaviors, biting is considered one of the ultimate defensive mechanisms (Duellman and Trueb 1986. Biology of Amphibians. McGraw Hill, New York, New York. 670 pp.).

We thank Fundação O Boticário de Proteção à Natureza / MacArthur Foundation for financial support, and CNPq for a fellowship. Instituto Florestal, Parque Estadual da Serra do Mar, allowed us to study anurans at the Núcleo Picinguaba. Célio F. B. Haddad commented on the manuscript and provided valuable information.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-Mouthed Toad). **MAXIMUM SIZE**. On 20 June 1992 an adult *Gastrophryne carolinensis* (39 mm SVL) was collected in T36N R18W Sec 1, Dallas County, Missouri, USA, by K. R. Toal and C. Sheil. This specimen (University of Kansas, KU 220524) exceeds the maximum size reported by Conant and Collins (1998. Reptiles and Amphibians of Eastern and Central North America. Third Ed. Expanded. Houghton Mifflin, Boston, Massachusetts. xviii + 616 pp.).

Submitted by **KEVIN R. TOAL**, Monsanto Company, 700 Chesterfield Parkway North, St. Louis, Missouri 63198, USA, and **JOSEPH T. COLLINS**, The Center for North American Herpetology, 1502 Medinah Circle, Lawrence, Kansas 66047, USA.

HYLA BERTHALUTZAE (NCN). **OVIPOSITION BEHAVIOR**. *Hyla berthalutzae* is a small treefrog with a distribution in the coastal lowlands from the State of Espírito Santo to São Paulo, and Serra do Mar, São Paulo, Brazil (Frost 1985. Amphibian Species of the World. Allen Press, Inc. and Assoc. Systematics Collections. Lawrence, Kansas. 732 pp.). From 29 reproductive modes

recognized by Duellman and Trueb (1986. Biology of Amphibians. McGraw-Hill Book Company, New York. 670 pp.), *H. berthalutzae* fits in mode 18: eggs arboreal, with hatchling tadpoles dropping into ponds or streams. Herein, we report oviposition behavior of this species in a temporary pond at Campo dos Escoteiros Geraldo Hugo Nunes (22°34'S, 43°02'W), Municipality of Magé, in the foothills of Serra dos Órgãos, State of Rio de Janeiro, southeastern Brazil.

The observations took place during the rainy nights of 17 September and 22 November 1996. The schedule of each mating sequence (ms) observed is in parenthesis. On 17 September, we observed a female approaching a calling male. When she jumped onto the same leaf where the male was calling, he immediately jumped on the female's back and grasped her in an axillary amplexus (ms-1, 2215 h). Then, the female carried the male onto another leaf (different from the male's perch) and remained on the middle of the leaf looking downward (ms-2). Only the female grasped the leaf. After a few minutes ($\leq$ 3 min), the pair in amplexus turned up and the female began to descend to the tip of the leaf (ms-3). On the tip of leaf, before liberation of eggs, the female alternately stretched and retracted her hind limbs (2227 h), perhaps verifying the leaf's end or signaling the imminence of liberation of eggs to the male (ms-4). At the moment of oviposition, the pair moved upward as several eggs were released in a thin gelatinous layer onto the top surface of the leaf (2231 h). After about five minutes, the male emitted a tenuous call (2238 h) and left the female (ms-5, 2242 h). The abandoned female began (2248 h) to push (or shake) the clutch with her hind limbs, alternating with intervals of rest (ms-6), for about 50 minutes, she then deserted the clutch. These movements appeared to push the clutch to the tip of the leaf. An alternative explanation suggests that this behavior may influence the fertilization of eggs by shaking the gelatinous mass. Some hours after oviposition the clutch remained hanging on the tip of the leaf above the pond; it had obviously increased in volume, likely influenced by rain or high humidity.

On 22 November, we observed another pair in amplexus. All of the mating sequences described above were observed. However, before amplexus the female performed mating sequences 2–4 alone. Afterwards, she established amplexus with a male that was ca. 40 cm away and then returned to the same leaf and spawned. Quantitative parameters of the clutches are (mean $\pm$ SD): number of eggs = 49 ± 10 (N = 11), diameter of eggs = 4.4 ± 0.5 mm (N = 20), clutch size: length = 4.4 ± 0.5 cm (N = 10), width = 1.8 ± 0.6 cm (N = 10), height above the pond = 24.4 ± 9.0 cm (N = 10).

We thank J. P. Pombal, Jr. and Ronaldo Fernandes for their critical reading of this manuscript, and Adriana Pugliese, Ana C. R. Alves, Luiz N. Weber, and Sérgio P. de Carvalho e Silva for assistance in fieldwork.

HYLA MICROCEPHALA (NCN). **HABITAT.** Many frogs utilize burrows of other animals to avoid heat or desiccation (Lips 1991. J. Herpetol. 25:477–481; Dundee 1999. Herpetol. Rev. 30:91–92), or create their own chambers in mud to aestivate (Duellman and Trueb 1986. Biology of Amphibians. J. Hopkins University Press, Baltimore, Maryland. 670 pp.). However, such behavior is unusual among hylid frogs (but see Tucker et al. 1995. Herpetol. Rev. 26:32–33). During the first two weeks of March 2001, I observed a total of eight small hylids (2.0–2.5 cm SVL) under rocks along the bank of Rio Las Marias, Venezuela (9°10'N, 69°44'W). Based on photos, these frogs have been tentatively identified as *Hyla microcephala* (W. E. Duellman, pers. comm.).

The locality was in the Andean piedmont where a small river (3–5 m wide, 0–1.5 m deep) passes through degraded deciduous forest. One bank was relatively flat and composed of sand, gravel, and cobbles, with many cobbles and small boulders at the surface. While searching under large rocks (10–30 cm diam) along the shoreline, I discovered several frogs. I continued to find them sporadically along a 200 m length of riverbank during a two-week period. Most observations were of a single frog occupying a rock, but two individuals were in contact under the same rock in one case.

As the water level steadily dropped during mid-March, I searched exhaustively for frogs under ca. 100 rocks situated at different distances from the river in an area of ca. 25 m^2. Only two rocks within 20 cm of the water line had frogs underneath, which roughly coincided with the distance at which the soil beneath the rocks remained visibly moist. Given that the rocks where I first observed *H. microcephala* were 2 m away from the water line by the time of the last observation, I infer that these frogs were relocating as the water dropped to stay in a humid environment. Despite working along the river daily during January–March 2001, my only observation of a *H. microcephala* not under a rock was a single individual seen at midnight near the shore in mid-March.

There was no evidence of burrowing near occupied rocks, hence *H. microcephala* probably used only rocks with pre-existing passages. There was no obvious evidence of extreme torpor or specialized secretions among the individuals observed. This is the first record of this species using underground refuges, and short-term use of shoreline rocks as refuges from the prevailing low humidity and high temperatures may have been critical for survival during this particularly dry year.

I thank W. Duellman for identifying the frogs from photos, A. Flecker for facilitating my work at Rio Las Marias, and H. Greene for helpful comments on this note.

PHLYCTIMANTIS KEITHAE (Wot-wot). **DEFENSIVE BEHAVIOR**. The African Hyperoliidae includes a clade of large terrestrial or climbing frogs in the genera *Kassina*, *Phlyctimantis*, and *Semnodactylus*. When disturbed, many display balling behavior; tucking the limbs in, bending the body forwards, and lowering the head with retracted eyes. We report on a novel anti-predator behavior shown by the wot-wot, *Phlyctimantis keithae*.

Phlyctimantis keithae is restricted to the Udzungwa Mountains, part of the Eastern Arc highlands of Tanzania. Locally the frog is common and known as a wot-wot, an onomatopeic form of the advertisement call. The back and sides are dark purple, with bright orange patches on the thighs. Observations were made at Luisenga,

a nature reserve and man-made lake within a tea plantation (08°36'51.2"S; 035°20'22.8"E, 1855 m) 8–9 November 1999. When disturbed by gentle prodding, the frog rapidly twists onto its back, throwing its limbs across the body (Fig. 1). The position is assumed so quickly that it would be appropriate to describe this action as snapping into position. The frog maintains this cryptic posture for about 20 sec, and then returns to typical position in one or two rapid intermediate jerks, holding each for a few seconds before returning to normal posture. Four frogs tested adopted similar positions. The animal holding this defensive pose looks quite un-froglike, displaying the orange patches and belly pattern, while keeping the eyes open.

Some observations are available for defensive behavior of two of the three other species of *Phlyctimantis*: *Phlyctimantis boulengeri* places the head between the forelegs, while raising the sacral region which displays the red coloration of the hind legs (Rödel and Ernst 2001. Alytes 18:178–186). Rödel and Ernst (*op. cit.*) report that the frog produces a sticky secretion over the skin. In Uganda, *P. verrucosus* secretes a bad-smelling thick mucus over the skin (Drewes and Vindum 1994. J. Afr. Zool. 108:55–70). None of the many *P. keithae* we have handled has produced any defensive mucus.

This behavior is sometimes referred to as "death-feigning," although in the case of the wot-wot the behavior would appear to result in camouflage, by either breaking up the outline or changing the overall shape of the animal, presumably to conflict with a predator search-image.

Although Rödel et al. (2000. Salamandra 36:125–130) did not observe similar behavior in the related *Kassina senegalensis*, *K. fusca*, or *K. cassinoides*, Rödel and Braun (1999. Biotropica, St Louis 31:178–183) record one subadult *K. fusca* lying on its back with limbs outstretched.

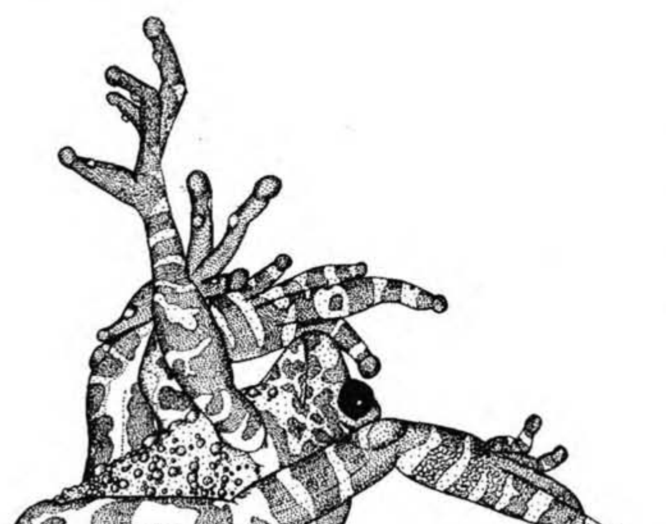

FIG. 1. Defensive posture assumed by *Phlyctimantis keithae* when disturbed. Drawn from a transparency.

The metamorphs of *Phlyctimantis keithae* are only known to ball. At Mufindi 10 metamorphs were found sheltering under a stone. Each was around 10 mm SVL. They resembled small spiders; the head and limbs were tucked in, with the bright orange patches showing. Related frogs we have seen balling include *Kassina kuvangensis* from northwestern Zambia, and *Kassina maculata*. Other reported examples include *Kassina lamottei* and one *K. cochranae* (Rödel et al. 2000., *op. cit.*), which remained in a ball for a few minutes, before slowly stretching out its limbs and moving off.

The Tanzania Commission for Science and Technology (COSTECH) is thanked for a research permit issued to AC. Greg Crutsinger prepared Fig. 1. Alison Channing is thanked for drawing our attention to this behavior in the field.

PHYSALAEMUS PUSTULOSUS (Tungara Frog). **HABITAT.** Use of burrows created by other animals is common among frogs (Cocroft and Hambler. 1989. Biotropica 21:2–8; Lips 1991. J. Herpetol. 25:477–481). In many cases, spider burrows are used by frog species that are apparently invulnerable to predation by the resident spider (Dundee 1999. Herpetol. Rev. 30:91–92). *Physalaemus pustulosus* use spider burrows in Mexico (Powell et al. 1984. Salamandra 20:273–274), and here I report use of an active crab burrow in degraded deciduous forest within the Andean piedmont of Venezuela (9°10'N, 69°44'W). Throughout a three-week period (late-January to mid-February) of the dry season in 2001, I observed a *P. pustulosus* using this burrow as a refuge.

The burrow opening was ca. 6 cm in diameter, but its depth was not ascertained. On most nights, a tungara frog was sitting near the entrance to the burrow. When I approached, it often retreated into the burrow. On many nights, a crab was also visible just inside the tunnel, but I was unable to capture it for identification. On one occasion, I approached the burrow near midnight and the frog retreated into the tunnel. When the tunnel was illuminated, I could clearly see the frog resting inside with the crab between the entrance and itself. The frog had moved over or under the crab as it retreated into the burrow. Continued checks of the burrow revealed no evidence of the frog or crab from mid-February through mid-March.

Burrowing terrestrial crabs have never been seen at this site despite intensive fieldwork during the last 15 years (A. Flecker, pers. comm.). Thus, the crab in question was likely to have been an aquatic species (probably *Sylviocarcinus piriformis*) burrowing upward from the ground water table. Crayfish burrows linking the soil surface and water table are known to harbor North American frogs during dry conditions (Neill 1951. Ecology 32:764–766) and winter (Carpenter 1953. Ecology 34:74–80). Some crabs consume *P. pustulosus* (Ryan 1985. The Tungara Frog. Univ. Chicago Press, Chicago. 230 pp.), but the unusually severe dry season of 2001 may have enhanced the value of this refuge.

I thank M. Ryan for identifying the frog, G. Pereira for identifying crab photos, A. Flecker for facilitating my work at Rio Las Marias, and H. Greene for helpful comments on this note.

PSEUDACRIS STRECKERI ILLINOENSIS (Illinois Chorus Frog). **SATELLITE BEHAVIOR**. Satellite behavior has been recognized in many anuran species (Robel 1985. J. Herpetol. 19:432–436). The short breeding season, limited range, and secretive lifestyle of *Pseudacris streckeri illinoensis* have left much of its natural history unknown. On 19 February 2002 we visited a chorus of *P. s. illinoensis* located about 2.5 km NW of Nimmons, Clay County, Arkansas, USA. The chorus was in a cotton field flooded with about 40 cm of water. Six aggregations of male *P. s. illinoensis* were observed. In each of these aggregations, a single male was calling from his perch while several non-calling males hovered within 15 cm of him. Aggregations ranged from 1 to 5 non-calling males (1, 2, 2, 3, 3, 5). Two aggregations were observed separately for about 5 minutes. One of the aggregations consisted of two satellites and the other had five satellites. In both cases only a single calling male was observed. In each instance none of the accompanying non-calling males vocalized despite incessant calling by the vocal male. All cases of apparent satellite behavior were observed in open water where isolated emergent vegetation (3–4 stems) was present. Along the south shore of this pond there was a large aggregation of about 25–30 males with plenty of emergent vegetation. In this area we could not determine if males were acting as satellites or not, although both calling and non-calling males were observed there. Based on these observations, satellite behavior may be facultatively expressed in response to available calling perches in this species. In this scenario, areas with few available calling perches would possess higher levels of satellite behavior, whereas in areas with a plethora of emergent vegetation the behavior should not be evident. Further investigations on the breeding biology and larval ecology of *P. s. illinoensis* are warranted in Arkansas.

Submitted by **MALCOLM L. McCALLUM**, Environmental Sciences Ph.D. Program, Arkansas State University, P.O. Box 847, State University, Arkansas 72467, USA (e-mail: mmccallu@astate.edu), and **ROBERT G. NEAL** and **STANLEY E. TRAUTH,** Department of Biological Sciences, Arkansas State University, P.O. PSEUDACRIS TRISERIATA (Western Chorus Frog) **and *RANA SYLVATICA*** (Wood Frog). **CHYTRIDIOMYCOSIS.** The chytrid fungus *Batrachochytrium dendrobatidis* is a known pathogen of anuran amphibians, and has been correlated with amphibian die-offs worldwide (Daszak et. al. 1999. Emerging Infectious Diseases 5:735–748). In Colorado, *B. dendrobatidis* has infected Boreal toads (*Bufo boreas)* (Muths et. al., *in review*) and has been identified on museum specimens of northern leopard frogs (*Rana pipiens)* (Carey et. al. 1999. Develop. Comp. Immunol. 23:459–472). We report the first verified case of chytrid fungus in chorus frogs (*Pseudacris triseriata)* and wood frogs (*Rana sylvatica)* in the United States. We collected seven *P. triseriata*, and two adult and two juvenile *R. sylvatica* in the Kawuneeche Valley in Rocky Mountain National Park (RMNP) during June 2001. These animals were submitted to the National Wildlife Health Center (NWHC) as part of an amphibian health evaluation in RMNP. Chorus frogs were shipped in one container. Wood frog adults and juveniles were shipped in two separate containers. Histological examinations of all chorus frogs and 3 of 4 wood frogs were positive for chytrid fungus infection. The fourth (adult) wood frog was too decomposed for meaningful histology. Histological findings consisted of multifocally mild to diffusely severe infections of the epidermis of the ventrum and hindlimb digital skin. Chytrid thalli were confined to the thickened epidermis (hyperkeratosis), were spherical to oval, and occasional thalli contained characteristic discharge pores or zoospores (Green and Kagarise Sherman 1999. J. Herpetol 35:92–103; Fellers et al. 2001. Copeia 2001:945–953). We cannot confirm that all specimens carried the fungus at collection, because infection may have spread from one individual to all other individuals in each container during transport. Further sampling of amphibians in the Kawuneeche Valley is warranted to determine the rate of infection and mortality in these populations.

These specimens are catalogued in the National Wildlife Health Center Archives, *P. triseriata* 4761-020 through 4761-024; *R. sylvatica* 4762-001 and 4762-002. This work was funded by the Amphibian Research and Monitoring Initiative and the National Park Service. We thank S. Street, R. Scherer, and T. Barnes for their field support.

RANA CURTIPES (NCN). **COLORATION**. In the present note, we report partial albino frogs and tadpoles of *Rana curtipes* from the Jog-falls area (14°13'N, 74°45'E) in the Western Ghat region (Karnataka, India). The normal or wild type adult *R. curtipes* is jet black except for a small golden brown patch on the dorsum. Tadpoles grow to a size of 75 mm and are jet black (Fig. 1A).

The population of *R. curtipes* occurring in the puddles of the Jog-falls area contain an albino strain mixed with the normal wild black type. The albinos are light orange or golden yellow, however their eyes are normal and black (Fig. 1A, B). Frazer (1983. Reptiles and Amphibians in Britain. Collins Publishers) considered such frogs as 'partial' albinos in contrast to true albinos having an orange skin and red eyes lacking melanin in the retina.

Field studies during February 1997 revealed that 13,804 of 13,852 tadpoles were black, with the remaining 48 (0.35%) of the semi-albino type. Ten of the partial albino tadpoles were reared with ten wild types (controls) in our laboratory. Periodic examinations during different stages of metamorphosis showed that both the wild and the partial albino types were near the same stages of

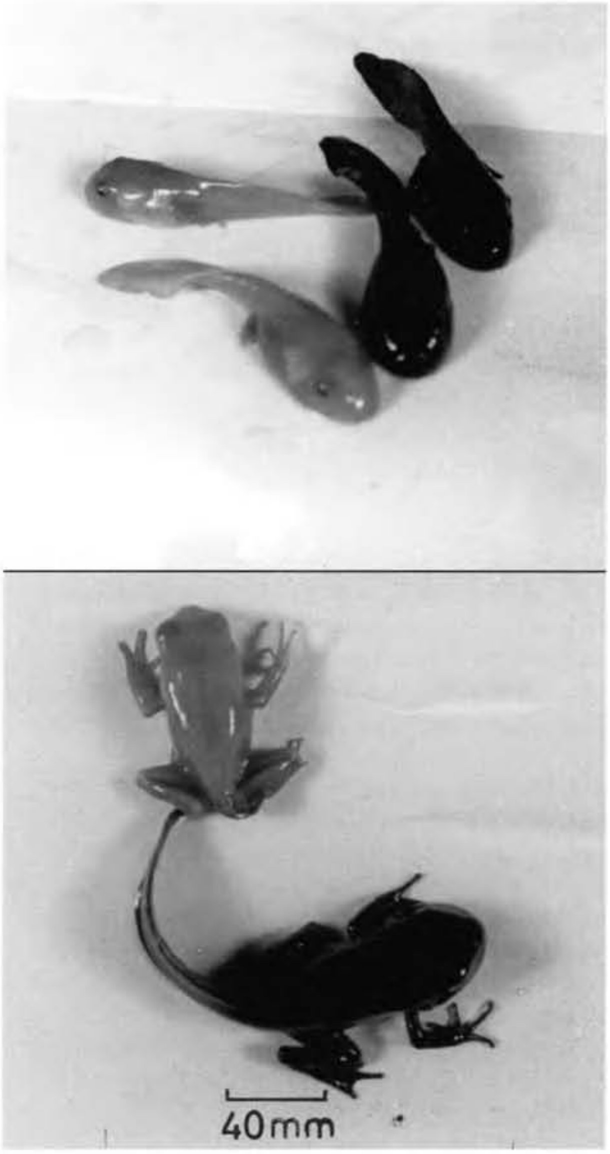

FIG. 1A–B. Live tadpoles and froglets of *Rana curtipes*. Tadpoles of wild type (black color) and of semi-albinos (orange-yellow); note the normal black eyes of the semi-albino type (A). Freshly collected wild (black in color) and semi-albino (orange-yellow in color) froglets of *Rana curtipes* (B).

development. All of the laboratory-reared tadpoles successfully completed metamorphosis. These findings are contradictory to those of Browder's (1972. J. Exp. Zool. 180:149–156) observation that albino *Rana pipiens* were less viable compared to their wild type siblings under the laboratory conditions. Further work on the demographic and ethological aspects of these semi-albino *R. curtipes* is in progress.

The laboratory facilities provided by Prof. V. P. Deshmukhe, and the field assistance provided by M. P. More of Karnatak Science College, Dharwad, are gratefully acknowledged.

RANA SYLVATICA **(Wood Frog). PHONOTACTIC STALKING.** On 30 January 2002, a breeding chorus of *Rana sylvatica* was observed at Stout Pond, a large woodland pond community that lies within a large depression in an oak-hickory forest in Stone County, Arkansas, USA (T16S R12W Sec 30) just south of State Hwy 14 and ca. 1.12 km E of the Baxter-Stone County line. A large breeding event had occurred the previous night, as ca. 10 x 15 m area of the pond was covered by egg masses, and many male wood frogs persisted calling in the pond. While observing *Pseudacris crucifer* and *R. sylvatica*, the following sequence of events was recorded.

A male *P. crucifer* was calling from a perch ca. 4–5 cm above the water in the fork of an upright emergent plant stem. A male *R. sylvatica* was observed facing this emergent plant from ca. 1 m away. The *R. sylvatica* slowly approached the plant where the *P. crucifer* was calling. Once the *R. sylvatica* reached the emergent stem, he began climbing up toward the still calling *P. crucifer*. The *R. sylvatica* pulled himself up the plant with his forelimbs, toward the calling *P. crucifer*, with his hind limbs freely floating in the water. Upon reaching the *P. crucifer*, the *R. sylvatica* nudged it with his snout causing it to cease calling. The moment the *P. crucifer* deflated its vocal sac, the wood frog grabbed him from his perch and escaped into the leaves and mud at the bottom of the pond. The *R. sylvatica* appeared to be homing in on the call of the *P. crucifer*. Whether phonotactic stalking is prevalent in pond communities where both these species breed is unknown; however, the large numbers of *P. crucifer* present at this site makes the species an available and nutritious food source for *R. sylvatica*.

Submitted by **MALCOLM L. McCALLUM** (e-mail: mmccallu@astate.edu), Environmental Sciences PhD Program, Arkansas State University, P.O. Box 847, State University, Arkansas 72467, USA, **TRACY L. KLOTZ** and **STANLEY E. TRAUTH** (e-mail: strauth@astate.edu), Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA.

RANA SYLVATICA **(Wood Frog). DEATH FEIGNING.** On 30 January 2002, a breeding chorus of *Rana sylvatica* was observed at Stout Pond, a large woodland pond community that lies within a large depression in an oak-hickory forest in Stone County, Arkansas, USA (T16S R12W Sec 30) just south of State Hwy 14 and ca. 1.12 km E of the Baxter-Stone County line. A large breeding event had occurred the previous night, as the area of the pond covered by egg masses was ca. 10 x 15 m, and many male wood frogs persisted calling in the pond. More that a dozen male *R. sylvatica* were observed performing a previously unreported behavior reminiscent of death feigning in *Acris crepitans* (McCallum 1999. Herpetol. Rev. 30:90).

When individual calling male wood frogs were disturbed, they would dive into the debris on the pond bottom. Upon reaching the substrate, they would remain motionless in the leaves where they could easily be picked up by hand. They positioned themselves so their abdomen and snout terminus were simultaneously in contact with the substrate. All the limbs were in their normal resting position but elevated from the substrate so the frog was resting on its venter. The medial digits of the forelimbs were positioned against the tympanum. The hind legs were similarly raised with the femo-

ral portions of the limbs held against the lateral flanks of the abdomen and the plantar region of the foot facing laterally. If the water surrounding a frog was stirred with a net, the animal remained in this position, allowing itself to drift with the current created by the investigator. Once captured, these frogs immediately ceased performing this behavior and proceeded to attempt escape as typically observed in these ranids.

KLOTZ** and **STANLEY E. TRAUTH** (e-mail: strauth@astate.edu), Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA.

RANA SYLVATICA (Wood Frog). **PARASITE.** On 21 August 2002, we captured a wood frog (*Rana sylvatica*; 31 mm SVL; 3.4 g) with grossly enlarged eyes in a pitfall trap in Elk Island National Park, Alberta, Canada (53°36'N, 112°53'W; Paszkowski et al. 2002. Research Links 10[1]:13, Parks Canada). Both eyeballs extended abnormally beyond the orbits, with skin on the posterior surfaces stretched taut (Fig. 1b); the eyeballs themselves did not seem to be enlarged, although the tissue surrounding them was swollen. The cornea of the left eye was clear, but the right cornea was covered with whitish tissue (probably including the lower eyelid) that obscured most of the iris and pupil (Figs. 1c–d). The animal had no other signs of deformities or injuries, and did not appear emaciated or stressed.

We returned the frog to the Health Sciences Laboratory, University of Alberta, Animal Services Unit. The animal was sacrificed, processed using standard histological techniques, and serial sections were made through the eyeball and associated tissues. Over 100 trematode mesocecariae were present within connective tissue behind each eyeball, enough that the cysts forced the eyes up and out of the orbits. A single cross-section through the connective tissue behind both eyeballs contained 60 trematodes. The serial sections were examined and based on key morphological traits (width of body and ventral sucker, location of acetabulum, oral spines), the mesocecariae were identified as possible members of the genus *Alaria* (Family Diplostomidae; Schmidt and Roberts 1996. Foundations of Parasitology. Wm. C. Brown Publishers, Dubuque, Iowa. 659 pp). Mesocecariae of *Alaria* sp. are commonly found in anurans, but are usually located between muscle fiber bundles in the hind legs (J. Holmes, pers. comm.).

FIG. 1. (a) Normal *Rana sylvatica*. (b–d) *R. sylvatica* with infestation of trematode mesocecariae behind eyeballs: dorsal (b), left (c), and right (d) views. Note tissue obscuring cornea in (d).

In 2001 we captured 25 wood frogs and 37 western toads (*Bufo boreas*) in pitfall traps at the same site as the parasitized wood frog, but no other individuals displayed any external signs of infestation. The infection seen in the wood frog collected at Elk Island National Park was unusual both because of the location of the parasites in tissue directly behind the eyeballs, and the severity of the infection.

Thanks to N. Nation and colleagues for initially examining and processing the specimen, and A. Shostak and J. Holmes for identifying the parasite. Parks Canada allowed access to the study site. Z. Eaton provided field assistance. Ducks Unlimited Canada, Friends of Elk Island, and Alberta Sports, Recreation, Parks, and Wildlife Foundation provided funding for amphibian sampling at Elk Island.

SCINAX ALTERA (NCN). **PREDATION**. Spiders, mainly Pisauridae, are important predators of frogs, with most predation events being reported from aquatic environments (Bastos et al. 1994. Herpetol. Rev. 25:118; ; Johnson 1996. Herpetol. Rev. 27:140; Rogers 1996. Herpetol. Rev. 27:75; Schiesari et al. 1995. Herptol. Rev. 26:30–31; Seely et al. 1990. Herptol. Rev. 21:89–90).

On March 2001 at 2035 h, we observed a juvenile male pisaurid spider, *Thaumasia* sp. (10.2 mm body length), that had just seized a juvenile *Scinax altera* (11.5 mm SUL) at the edge of Cabiúnas Lagoon in the Restinga de Jurubatiba (22°17'S; 41°41'W), Macaé, Rio de Janeiro State, Brazil. The spider was on the water surface grasping the anuran by its back using its pedipalps, whereas the frog had its body submerged and was apparently dead. Because this spider usually lives near or on the water surface, our observations indicate that even juvenile spiders may constitute an important source of mortality for *Scinax altera*, especially post-metamorphic and juveniles living at this breeding site.

Renner L. C. Baptista (Invertebrate Department, Aracnology Section) and J. P. Pombal Jr. (Vertebrate Department) of the Museu Nacional do Rio de Janeiro identified the spider and the frog, respectively. This research was supported by CNPq and FAPERJ.

CROCODYLIA

CAIMAN LATIROSTRIS (Broad-snouted Caiman). **FEEDING.** *Caiman latirostris* feeds on diverse prey, which consist mostly of arthropods (insects), snails, crabs, and frogs (A. Imhof, unpubl. data). Although the species is opportunistic (Magnusson et al. 1987. J. Herpetol. 21:85–95; Pooley 1989. *In* C. A. Ross [ed.], Crocodiles and Alligators, pp. 76–91. Golden Press. Silverwater, Australia), as with other crocodilians, size (Delany and Abercrombie 1986. J. Wildl. Mgmt. 50:348–353) and mouth morphology (Singh and Bustard 1982. British J. Herpetol. 6:253–258) influence its feeding behavior. In particular, the wide and short snout of *C. latirostris* appears better suited to crushing rather than as a tool for active foraging (Verdade et al. 1992. *In* L. M. Verdade and A. Lavorenti [eds.], Anais do II Workshop sobre Conservação e Manejo do Jacaré-de-Papo-Amarelo [*Caiman latirostris*], pp. 77–91. ESALQ / USP, Piracicaba, Brazil). Here, we report a passive feeding behavior that, to our knowledge, is unreported in *C. latirostris*.

In November 1998, during a routine night count for caimans at Estancia 'El Estero,' Santa Fe, Argentina (30°03'S, 59°58'W), we observed a caiman (presumably an adult male based on size) at the discharge of a small dam (ca. 0.60 m high), constructed for watering cattle. The caiman allowed the discharge stream to pass through its open mouth. As we assumed that it was waiting for a prey item to fall into its mouth, we spent 15 min observing it. Whenever an item fell into its mouth, the caiman immediately closed its mouth and swallowed. We saw this behavior four times, but we were unable to identify individual prey. Based on other data (King et al. 1998. Cooperative feeding, a misinterpreted and under-reported behavior of crocodilians. Available at: http://www.flmnh.ufl.edu/natsci/herpetology/crocbiology/bartram.htm; Pooley, *op. cit.*; Schaller and Crawshaw 1982. Copeia 1982:66–72), we suspect that most were fishes.

Similar passive feeding behavior has been reported in *Caiman yacare* (Schaller and Crawshaw, *op. cit.*), *Alligator mississippiensis* (King et al., *op. cit.*), and *Crocodylus niloticus* (Pooley, *op. cit.*), but these observations each involved more then one crocodilian fishing together cooperatively. Our observations suggest that *C. latirostris* feeding behavior is more diverse than previously recognized. Diefenbach (1979. Copeia 1979:162–163) reported that *C. latirostris* dug in the bottom of aquatic sites to feed on snails, but passive feeding had not been reported. Our observation also documents broad-snouted caiman occupation and use of man-made water structures.

We thank A. Woodward and W. King for their suggestions.

TESTUDINES

CHELYDRA SERPENTINA (Common Snapping Turtle). **DEFORMITY**. On 11 June 2000, an adult female *Chelydra serpentina* (210 mm carapace length, weight 1.70 kg) was collected by Nicholas D'Angelo in a drainage canal on West Napoleon Avenue in Metairie, Louisiana, USA and brought to the Audubon Zoo New Orleans the following day. The carapace and plastron were transversely constricted at mid-body by a plastic ring (142 mm circumference), the type found on milk and water containers (Fig. 1). The ring apparently became lodged on the turtle as a juvenile, causing the constriction as the turtle grew, resulting in this unusual deformity. The ring was removed from the turtle after capture. Two similar cases of this deformity in *Trachemys scripta elegans* (Red-eared slider) have been documented (Odum 1985. Herpetol. Rev. 16:113; McLeod 1994. Herpetol. Rev. 25:116–117). This is the first known instance to occur in *C. serpentina*.

The turtle was taken to the zoo's animal hospital where radiographs indicated that she was gravid with 12 eggs, all located on the posterior side of the constriction (Fig. 2). The eggs were oviposited on 23 June 2000 and set up for incubation. One turtle pipped on 17 September 2000 but died before completely emerging from the egg. The remaining eggs were infertile and addled.

FIG. 1. Lateral view of *Chelydra serpentina* showing plastic ring around constriction site.

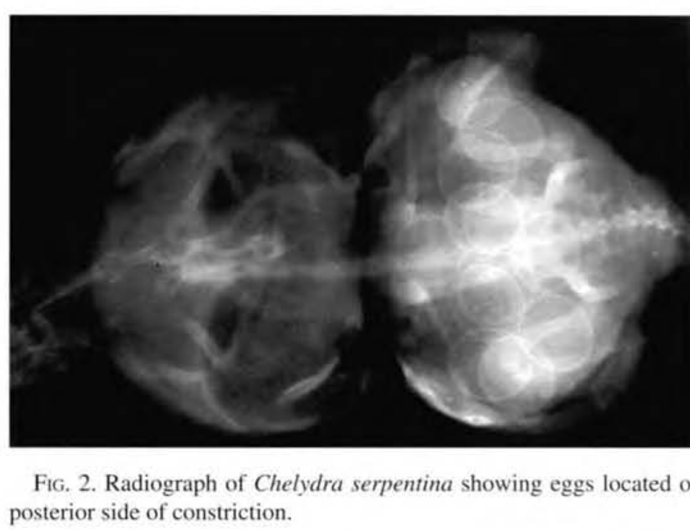

FIG. 2. Radiograph of *Chelydra serpentina* showing eggs located on posterior side of constriction.

DERMOCHELYS CORIACEA (Leatherback Sea Turtle). **STRANDING**. To date, only two strandings of *Dermochelys coriacea* are known from the Belgian coast. The first one took place in December 1988 (Van Gompel 1989. De Strandvlo 9:102). The second was reported by Haelters and Kerckhof (1999. De Strandvlo 19:30–39). This specimen (total straight-line length ca.170 cm) was cut in two sub-equal parts, most probably by a ship's propeller. The two parts were found a few km apart (off De Haan in trawler nets and on Wenduine beach) on 10 and 11 September 1998. Its skeleton is registered as IRSNB 15129. A third case, here reported, occurred on 19 December 2000, at Mariakerke (Ostend). The still-alive but dying male specimen (carapace curved length 157 cm, total length 194 cm, weight 369 kg), stranded in the evening, was brought to the Blankenberge Sea Life Center where it died during the night. An external examination revealed numerous deep cutaneous lacerations on the ventral and lateral sides of the animal. The internal examination revealed subcutaneous muscular hematomas and muscular degeneration, internally of the cutaneous lacerations. Evidence of focal hepatic necrosis and acute fibrineous peritonitis was also observed. The hepatic lesion and the peritonitis probably both occurred as a consequence of the cutaneous lacerations. The digestive tract was empty. The injuries, from which the animal eventually died, can be attributed to the impact of a ship or a ship's propeller. Mouldings of the whole specimen and its mouth were made by Zephyr Co. (Wellem, Belgium). Cast and skeleton are in the collections of the IRSNB (IRSNB 15516). The heart and samples for histopathology are kept at the Pathology Department of the Faculty of Veterinary Medicine of the Université de Liège. Some *Stomatolepas dermochelys* (Crustacea: Cirripedia) were collected from this animal and the one stranded in 1998 and are deposited in the collections of the IRSNB.

GOPHERUS AGASSIZII (Desert Tortoise). **CALICHE MINING**. *Gopherus agassizii* have been observed ingesting bone, stones, and soil (reviewed by Esque and Peters 1994. *In* Bury and Germano (eds.), Biology of North American Tortoises, pp. 105–111. Natl. Biol. Surv., Fish Wildl. Res. 13, Washington, D.C.). Desert tortoises may scrape topsoil to access caliche (a source of calcium, as calcium carbonate [Krauskopf 1979. Introduction to Geochemistry. McGraw-Hill Book Co., New York, 617 pp.]) and may alter regular movement patterns to visit such mineral sources (Marlow and Tollestrup 1982. Anim. Behav. 30: 475–478). To date, observations of caliche mining and other means of calcium acquisition (i.e., ingestion of bone) have been documented in adult tortoises of both sexes. Here we report an instance of suspected caliche mining by juvenile desert tortoises.

On August 2, at 1733 h, we observed 3 juvenile desert tortoises (61-, 63-, and 114 mm midline carapace length [MCL]) facing a sheer caliche wall immediately adjacent to a primitive road east of Tucson, Arizona (32°08'N, 110°41'W). All tortoises were within one meter of each other and within 0.5 cm of the wall. The animals were captured, weighed, and measured; a white powder was noted on the beaks of all 3 tortoises. The fine powder formed 3mm-wide rings around their mouths. A fourth juvenile (70 mm MCL) was captured ca. 5 m from the others, walking in the direction of the caliche wall. This tortoise did not have white powder surrounding its mouth. These individuals presumably came to this site to access a calcium source.

GOPHERUS AGASSIZII (Desert Tortoise). **ELEVATIONAL RANGE**. The Sonoran Desert population of the desert tortoise (*Gopherus agassizii*) inhabits rocky slopes and foothills in the desertscrub community of the Sonoran Desert. Desert tortoises in Arizona are most commonly found between 300–1067 m with a maximum recorded elevation of 1615 m (Ariz. Game and Fish Dept., unpubl. data). In the Mojave Desert population of this species, the maximum recorded elevation is 2200 m (Grover and DeFalco 1995. USDA For. Ser. Gen. Tech. Rept. INT-GTR-316. 134 pp.). High mountains are usually considered inappropriate for tortoise habitation, although some individuals range into juniper woodland communities. On 20 July 2000, a desert tortoise was observed and photographed by the two senior authors at an elevation of 2380 m in the Rincon Mountain District of Saguaro National Park, Pima County, Arizona, USA. The tortoise was actively moving on a trail in a ponderosa pine-dominated coniferous community. It seems unlikely that humans transported the tortoise to this location, which is within a road less national park wilderness area that receives < 300 visitors per year. The nearest road is 13.9 km by trail from this location and > 600 m lower in elevation.

KINIXYS HOMEANA (Home's Hingeback Tortoise). **PREDATION.** Field records of tortoises predated by snakes are few, both in temperate and in tropical environments (e.g., Rugiero and Luiselli 1995. Amphibia-Reptilia 16:407–411). Indeed, during our long-term studies on the ecology of forest snakes in southern Nigeria, we analyzed stomach contents of hundreds of snakes from more than 30 species (e.g., see Luiselli et al. 1998. J. Zool. (London) 246:125–133; Luiselli et al. 2002. Can. J. Zool. 80:55–63), but did not find any tortoise item as prey. Here we report two cases of predation by snakes upon *Kinixys homeana*, a species found in the rainforests of southern Nigeria (Luiselli et al. 2000. Rev. Ecol.

Terre et Vie 55:3–23).

On 8 April 2001, a villager from Degema (Rivers State, 04°48'N, 06°48'E) carried to us a recently killed, large male Blanding's tree snake (*Toxicodryas* (= *Boiga*) *blandingi*), 168.7 cm SVL, with an obviously enlarged stomach. The snake, which was killed at a site where secondary forest intergraded into a small pineapple plantation, was dissected after routine measurements. It contained the remains of a large male *Agama agama* (common prey for this snake: cf. Luiselli et al. 1998. Amphibia-Reptilia 19:430–436; Hughes 2000. Herpetol. Bull. 74:8–11), and a recently ingested juvenile *Kinixys homeana*. This tortoise measured 11.4 cm in plastron length, and had been ingested head first.

On 17 November 2001 while searching for snakes in a secondary forest near Ogbele (Rivers State, 05°00'N, 06°50'E), we found a Gold's tree cobra (*Pseudohaje goldii*) coiled under an artificial plastic cover-object routinely used by us for sampling snakes. The snake was captured, sexed, measured, marked by ventral scale-clipping, and examined for prey items by palpation of the abdomen. The snake, a male 174.5 cm SVL, regurgitated the remains of the posterior side of the body of a male *Kinixys homeana*. The tortoise was clearly ingested head-first. Based on comparisons with live materials of the same tortoise species, we estimated that the prey would have been ca. 14 cm in plastron length. Photographs of both prey items have been deposited at the Nigerian Agip Oil Company Ltd. environmental office (Victoria Island, Lagos).

Toxicodryas blandingi and *Pseudohaje goldii* both are semi-arboreal species with an eclectic and opportunistic dietary spectrum (Luiselli et al. 1998. Amphibia-Reptilia 19:430–436; Pauwels et al. 1999. Afr. Herp. News 30:32–33), and in both cases noted here the predator was a large adult specimen. Thus, it may be hypothesized that tortoise predation, albeit a rare event, is perhaps confined to the larger-sized population cohorts of these opportunistic snakes.

We are indebted to several companies of the E.N.I. Group, F.I.Z.V., and Institute Demetra, for funding our long-term ecological research in Nigeria. Chelonian Research Foundation (through its Linnaeus Fund Annual Turtle Research Award, years 1999 and 2000) supported the "*Kinixys* conservation ecology project" of which this note is an outcome. M. Capula, E. Filippi, and L. Rugiero critically commented upon a previous draft of the manuscript.

STERNOTHERUS ODORATUS (Common Musk Turtle) and ***CHELYDRA SERPENTINA*** (Common Snapping Turtle). **REPRODUCTION.** Common musk turtles are known to have great plasticity in nesting behavior. Females may lay eggs on open ground, in shallow nests under leaf litter, or in fully-formed excavations (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C.). Moreover, the sharing of nesting sites by female conspecifics has been well documented (reviewed in Ernst et al., *op. cit.*). Here we report the use of nest excavations by *Chelydra serpentina* as nesting sites by *Sternotherus odoratus* in southeastern Michigan.

On 7 June 2000, we discovered a clutch of 7 *Sternotherus odoratus* eggs buried in loose sand within a large nest cavity on an earthen dam at Cedar Lake, Livingston Co., Michigan, USA. Soil disturbance adjacent to the nest indicated that the cavity had been recently dug and abandoned by a female *Chelydra serpentina*. On 10 June 2000, on another earthen dam on private property in Sylvan Township, Washtenaw Co., Michigan, we observed a female *S. odoratus* investigating a nest cavity dug the previous day by a female *C. serpentina* and whose eggs we had subsequently removed. The female was then later observed inserting the posterior portion of her body into the cavity, but did not deposit her eggs. Finally, on 11 June 2002, at the dam site in Washtenaw Co., we observed a female *S. odoratus* nesting adjacent to a nesting female *C. serpentina* within a small (ca. 70 cm diam) patch of sand where three clutches of *C. serpentina* eggs had been laid and subsequently removed by us in the preceding two-day period. The female deposited a clutch of 6 eggs within one of the empty nest cavities.

We thank David and Becky Schultz for access to their property. Turtle eggs were collected with permission of Michigan Department of Natural Resources, scientific collecting permit #CO868.

TERRAPENE CAROLINA BAURI (Florida Box Turtle). **REHYDRATION.** On 15 May 2002 at 1630 h, we discovered three *Terrapene carolina bauri* that had fallen down a brick-lined well on Egmont Key, Hillsborough County, Florida, USA. The smooth-sided well was 75 cm deep and 1 m in diameter, had a dry leaf litter floor, and effectively prevented escape. The turtles were extremely lightweight and dehydrated. Field body measurements of the three animals were: male, 132 mm carapace length (CL), 253 g; male, 120 mm CL, 233 g; juvenile male, 111 mm CL, 138 g. The large male was lethargic, whereas the smaller animals attempted to walk away. All three turtles were returned to the ranger station and provided with fresh water ad libitum until 0800 h the next morning. Re-measurements 14 h after initial capture showed that the 132 mm male drank 52 g of water to increase his mass to 305 g; the 120 mm male drank 32 g of water to increase to 265 g; and the juvenile male drank 20 g of water to increase to 158 g. All were alert and energetic upon release the day after initial capture. Based on data collected between 1991 and 2002 on Egmont Key, mean weights of box turtles of these size classes and sex/life stage are 353 g (N = 62 observations of 132 mm CL males), 266 g (N = 28 observations of 120 mm CL males), and 217 g (N = 11 observations of 111 mm CL juveniles). These data suggest that both the largest and smallest dehydrated turtles may not have fully hydrated upon release, although depleted fat reserves also may account for the below-average body mass. No data are known to us on how much body water a turtle can lose before it dies of dehydration

(but see Ross 1977. Comp. Biochem. Physiol. 56A:477–480; Chessman 1984. Aust. J. Zool. 32:649–655 for information on rates of evaporative water loss and time to recovery in laboratory settings). Under controlled conditions, Rose (1969. Southwest. Nat. 14:67–72) found that *T. ornata* lost 3.5% of their mass in six days without available water at a relative humidity of 18–22%. Although we do not know how long the three box turtles were in the well, park rangers told us that there had been no appreciable rainfall since at least March; Winter 2001 to late Spring 2002 was an exceptionally dry period in west-central Florida. The fact that Florida box turtles can drink from 13.7 to 20.5% of their initial body mass after forced dehydration suggests that they may be adapted physiologically to survive long periods without drinking water.

We thank Vic Hutchison for his insights into turtle water balance and its associated literature.

Submitted by **C. KENNETH DODD, JR.** and **MARIAN L. GRIFFEY**, Florida Caribbean Science Center, United States Geological Survey, 7920 Northwest 71st Street, Gainesville, Florida 32653, USA.

TERRAPENE ORNATA (Ornate Box Turtle). **SUMMER REFUGIUM.** Oppressive summer heat and drought in the southern United States is known to have a detrimental effect on wildlife in general. However, many animals including box turtles are known to escape the effects of the heat by retreating into burrows. On 30 June 1999 at 2225 h near Falls Road, ca. 0.4 km W of Hwy 1189, Hood County Texas, USA, an adult male *Terrapene ornata* was found in the recess of a shelved layer of limestone with a depth of ca. 25 cm. At the back of the recess a small pool of water was present with a depth of no more than 5 mm. Five adult *Rana berlandieri* were also present in the recess.

Submitted by **CARL J. FRANKLIN**, 1001 Denmark Drive, Grand Prairie, Texas 75050, USA; e-mail: Herpking@ix.netcom.com.

TERRAPENE ORNATA LUTEOLA (Desert Box Turtle). **HIGH ELEVATION RECORD.** On 28 July 2001 at 1030 h we observed an adult *Terrapene ornata luteola* in a relatively exposed tributary of Sunnyside Canyon (31°25'25"N, 110°21'37"W), Huachuca Mountains, Cochise Co., Arizona, USA, at an elevation of ca. 2180 m. The habitat consisted of pine-oak forest in mountainous terrain. Stebbins (1985. A Field Guide to Western Reptiles and Amphibians, 2nd Ed, Houghton Mifflin Co, Boston, Massachusetts, 336 pp.) lists maximum elevation at ca. 2010 m and states that *Terrapene ornata* is "primarily a prairie turtle. Over much of its range it inhabits treeless plains and gently rolling country grown to grass or scattered low bushes where the soil is sandy. Also occurs in open woodland." In Arizona, *T. o. luteola* occurs in oak woodlands and mesquite bosque, and the populations there apparently are showing a plasticity in habitat use that has not been reported elsewhere (M. Tuegel, USFWS, pers. comm.) Our observation represents an elevational increase of ca. 170 m and occurrence in a habitat hitherto unreported for Arizona populations of *T. o. luteola*.

LACERTILIA

CNEMIDOPHORUS SEXLINEATUS (Six-lined Racerunner). **MAXIMUM SIZE.** The reported maximum size for *C. sexlineatus* is 75 mm SVL and 241 mm total length (sex and locality unspecified; Conant and Collins 1998. Peterson Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd Edition Expanded. Houghton Mifflin Company, Boston, Massachusetts. 616 pp.). Here, we report a new size record for this species from Missouri.

On 16 August 1991, Kevin R. Toal and Randall S. Reiserer collected an adult female *C. sexlineatus* in an Ozark glade under a limestone rock along Route E, 1.8 mi. E of Route M (T21N, R26W, Sec 2) in Barry County. This individual was 84 mm SVL and 267 mm total length, which exceeds the current size maximum by 9 mm for SVL and 26 mm for total length. The specimen was deposited in the Natural History Museum, University of Kansas, Lawrence (KU 218611).

The specimen was collected with a Missouri Department of Conservation Scientific Collecting Permit issued to Kevin R. Toal.

COLLINS**, Kansas Biological Survey, University of Kansas, 2021 Constant Avenue, Lawrence, Kansas 66047, USA (e-mail: jcollins@ku.edu).

SERPENTES

AGKISTRODON CONTORTRIX CONTORTRIX (Southern Copperhead). **ENDOPARASITES.** An adult female *Agkistrodon controtrix contortrix* (57 cm total length; 215 g mass) was captured on 4 April 1998 in Randolph County, Georgia, USA, and later transferred to Central Florida Zoological Park on 18 April 1998. The snake was maintained in a glass aquarium with a perforated (3 mm holes) tight-fitting sheet metal lid. Newspaper was used as a substrate and the snake was fed freshly killed laboratory mice at two-week intervals.

Reports of *Cuterebra* (bot fly) infecting reptiles are lacking, as typical hosts are endothermic. However, on 24 June 1998, a third larval instar *Cuterebra* (ca.15 x 9 mm) was found in the snake's aquarium on the newspaper substrate (Fig. 1). The species was not determined, as accurate identification cannot be made from larvae. The *A. c. contortrix* was examined and a small lesion was located midbody, on the right ventrolateral aspect. The lesion was not septic and healed uneventfully.

Two weeks prior to this event, the snake had been restrained in a plexiglass tube for veterinary examination. No skin or body abnormalities were noted. This finding was inconsistent with *Cuterebra* infection as normally there is a lump in the skin where the "warble" is located and a breathing hole is present which is surrounded by inflammation. This lack of obvious cutaneous involvement suggests the possibility that the larva was in the process of emerging from a mammalian prey item, possibly a cotton mouse

(*Peromyscus gossypinus*), at the time the prey was ingested by the snake. Subsequently, it may have emerged from the mouse and attached itself to the lining of the snake's esophagus, eventually migrating out through the body wall. The prevalence of *Cuterebra* in cotton mice in Georgia ranges from 10 to 59% during the year (Durden 1995. Parasitology 81:787–790).

It is significant that the normal period for the larval development of *Cuterebra* is three to five weeks (Catts 1967. J. Med. Entomol. 4:87–101) and the period of time from when the snake was first captured to larval emergence noted here was about eleven weeks. This extended period of time may be attributed to the challenges of exiting from the gastrointestinal tract of an abnormal host. Although accidental hosts of *Cuterebra* have been reported, their suitability as hosts is limited in that only partial larval development usually occurs (Catts 1965. Trans. 30th North Am. Wildlife Nat. Resources Conf. Wash., D.C. 30:184–186). However in this occurrence, *A. c. contortrix* acted as a successful *Cuterebra* host as the larva was able to emerge and appeared to be the size of a fully developed third instar.

The *Cuterebra* larva reported here (HWML 16389) has been deposited in the collection of the Harold W. Manter Laboratory, Division of Parasitology, Nebraska State Museum.

We thank Kevin Enge for providing the *A. c. contortrix* with collection data and Darryl J. Heard for his assistance with this project.

FIG. 1. *Cuterebra* instar following emergence from an *Agistrodon contortrix contortrix*.

AGKISTRODON PISCIVORUS LEUCOSTOMA (Western Cottonmouth). **DIET**. We observed an adult female *Agkistrodon piscivorus leucostoma* (54.5 cm SVL; 317 g body mass) regurgitate a partially digested *Coluber constrictor* (100 g body mass) on 29 June 2001 at the Center for Biological Field Studies (CBFS), Walker Co., Huntsville, Texas, USA. The cottonmouth was observed and captured within a meter of a radio-tagged *A. p. leucostoma* (Zone 15; Phelps Quadrangle; UTM $^{340}38^{47}$ m N, $^{2}63^{334}$ m E).

Cottonmouths are known to prey on several snake species including *Nerodia*, *Thamnophis*, *Storeria*, *Farancia*, *Crotalus*, and *Agkistrodon* (Gloyd and Conant, 1990. Snakes of the *Agkistrodon* Complex. SSAR, Oxford, Ohio. 614 pp.). To our knowledge predation on *C. constrictor* has not been reported. The western cottonmouth's prey item (*C. constrictor*) has been deposited in the Herpetological Collection of the Sam Houston State Vertebrate Museum (SHSVM #H-0005-01).

VITT**, Sam Noble Oklahoma Museum of Natural History and Department of Zoology, University of Oklahoma, Norman, Oklahoma 73019, USA, and **WILLIAM I. LUTTERSCHMIDT**, Department of Biological Sciences, Sam Houston State University, Huntsville, Texas 77341, USA.

ANTARESIA MACULOSA (Spotted Python). **REPRODUCTIVE OUTPUT**. The genus *Antaresia* comprises the smallest pythons in the world; typical total lengths average less than one meter among free-ranging individuals. Reported clutch sizes vary by species, but average 6.5–12.6 eggs with a known extreme of 19 eggs in *A. maculosa* (Shine and Slip 1990. Herpetologica 46:283–290). Here I report an exceptionally large clutch of eggs from a captive spotted python.

On 02 April 2002, a captive-born *A. maculosa* (1215 mm snout–vent length) produced a clutch of 25 eggs after a remarkably long gestation (mating had occurred on 05 December 2001). The total clutch mass was 319 g, recorded < 8 h after oviposition. Two of the eggs (5.8 and 5.1 g) were obviously infertile, but the remaining 23 eggs appeared fertile (average mass of fertile eggs = 13.4 g). The female's post-partum mass was 667 g, such that relative clutch mass was 0.32 (calculated following Seigel et al. 1986. Herpetologica 42:179–185). The female was found coiled around the clutch. I did not observe shivering thermiogenesis as has been reported in other pythons. The eggs were removed and artificially incubated, but the majority of the eggs were lost to desiccation after an incubator malfunction. Seven neonates emerged from the surviving eggs between 04 and 07 June; these individuals averaged 8.0 g and 233 mm in snout–vent length. Despite the high number of eggs in this clutch, individual egg masses were similar to egg masses from other clutches from this colony of *A. maculosa*, thus providing no evidence of an intraspecific trade-off between offspring size and number. Similarly, while the body size of the dam approaches the maximal known for the species, females of similar sizes in the colony have not produced clutches of this size. This clutch size is higher than the maximal recorded clutch size of all but two species of Australasian pythons (Shine and Slip 1990, *ibid.*); both of the latter were produced by much larger-bodied pythons of the genus *Morelia*.

Research was aided by Contract DE-AC09-76SROO-819 between the U.S. Department of Energy and the University of Georgia's Savannah River Ecology Laboratory and with Financial Assistance Award Number DE-FC09-96SR18546 from U.S.

Department of Energy to the University of Georgia Research Foundation.

BOA CONSTRICTOR (Boa Constrictor). **MAXIMUM BODY SIZE.** Maximum body size for large constrictors has often been a topic of interest in herpetology and is one of the most frequently asked questions of herpetologists by the public. Boos (1992. Brit. Herpetol. Soc. Bull. 40:15–17) suggested that the record length for *Boa constrictor* is 4.2 m and that previous reports of larger specimens involved green anacondas (*Eunectes murinus*). We here report a new record length *Boa constrictor*. The specimen (YPM 12530) is a skin donated by A. P. Rogers on 31 July 1928 and was collected from Brazil. Though the skin had been prepared as a dry specimen by traditional means at the time, stretching does not appear to have affected the specimen's length as the middorsal scales overlap normally (Fig. 1). Mid-line straight length of the re-hydrated specimen is 4.45 m.

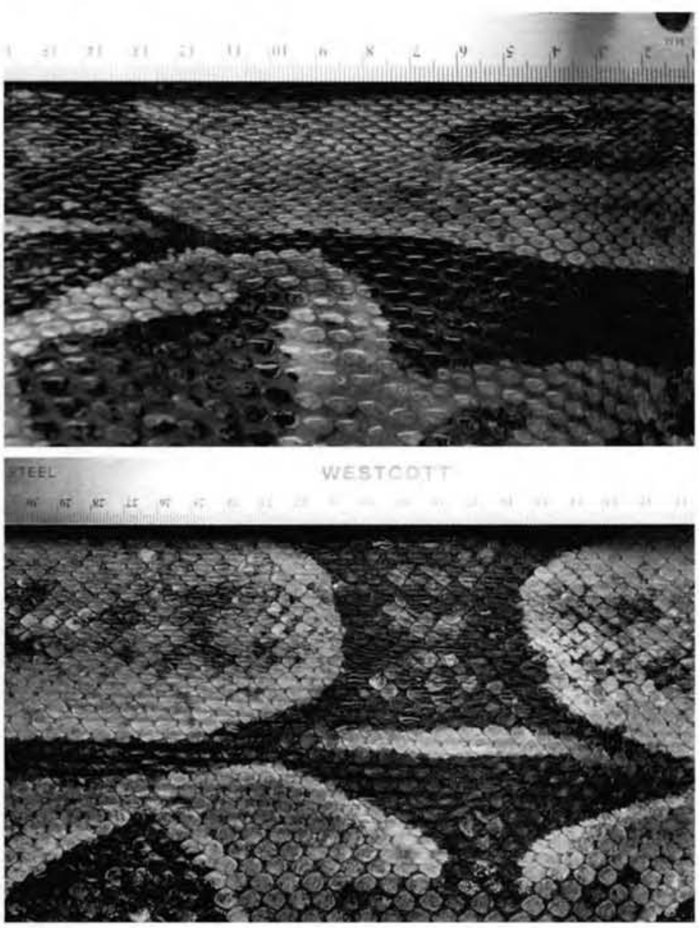

FIG. 1 Dorsal view of *Boa constrictor* dried skin (YPM 12530); occipital region (top) and mid-body (bottom) of YPM 12530. Scales at midline overlap normally.

Submitted by **GREGORY J. WATKINS-COLWELL** (e-mail: gregory.watkins-colwell@yale.edu) and **TWAN A.A.M. LEENDERS** (e-mail: twanleenders@scinax.com), Division of Vertebrate Zoology, Yale Peabody Museum of Natural History, 170 Whitney Avenue, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA.

BOTHROPS ASPER (Terciopelo). **PARTURITION**. Observations of snakes giving birth or laying eggs in the wild are rarely documented. On 29 August 1995 at 1200 h, one of us (MPS) encountered a female *Bothrops asper* 220 cm in total length basking in full sunlight on a log covered with lianas. The log was 1 m above the water level (just above eye level while sitting in a canoe) in Laguna de Zacatal in Estación de Biología Tropical Los Tuxtlas, San Andres Tuxtla, Veracruz, México. The snake was loosely coiled, just two coils, with her slightly-elevated head in the center of the coil and the tail on the outside of the coil. The tail was parallel to the log, not upraised. The snake was located when it hissed on being disturbed in our search for frog nests. The female exhibited continuous contractions of the muscles along the posterior half of her body for the entire time she was giving birth. Some of the young remained on the log and lianas while others fell into the water as they were born and immediately submerged out of sight. The female continued giving birth until 1430 h at which time she entered the laguna and swam at the surface for 10 m before leaving the water and entering the forest.

During this 2-h interval 35 young were born. Because litter size often reaches 80 for adult females of this size in this population (Buttenhoff and Vogt 1997. *In* E. Gonzales, R. Dirzo, and R. C. Vogt [eds.], Historia Natural de Región de Los Tuxtlas, pp. 478–480. UNAM, Mexico D.F.), we surmise that a significant number of offspring had already been born prior to the start of our observations. Assuming the rate of newborn emergence was relatively steady throughout, it probably took about 5 hours to give birth to the entire brood. Additionally, it is interesting that this primarily nocturnal snake should give birth during daylight hours in a relatively exposed situation.

Submitted by **MARCELO PAXTIAN SINACA** and **RICHARD C. VOGT***, Estación de Biología Tropical Los Tuxtlas, Instituto de Biología, Universidad Nacionial Autonoma de México, Apt. Post 94, San Andres Tuxtla, Veracruz, México 95700. *Present address: Coordinação de Pesquisa em Biologia Aquatica, Instituto Nacional de Pesquisas da Amazônia, Manaus, Amazonas, Brazil 69011-970 (e-mail: vogt@inpa.gov.br).

BOTHROPS ATROX (Common Lancehead). **PREY.** The diet of *Bothrops atrox* from Central Amazonia consists mainly of mammals, frogs, and lizards (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150). Here we report an observation of a freshwater eel, *Symbrachus* sp. (Gymnotidae), as prey of *B. atrox*. The snake was an adult female (IB 60751, 1112 mm SVL, broken tail, 560 g mass) collected in the region of "igapó" forests at Rio Jaú, Novo Airão, Amazonas, Brazil. The fish (ca. 320 mm total length, ca. 35–40 g mass) was ingested head-first and its anterior region was partially digested. Gymnotid eels migrate through the seasonally flooded floor of igapó forests, becoming exposed to terrestrial predators. This is the first record of a fish as prey of *Bothrops* and confirms the opportunistic feeding habits of *B. atrox*.

The fish was identified by J. Zuanon and F.C.T. Lima. Financial

support for the study at Rio Jaú was provided by Fundação Vitória Amazônica and Universidade do Amazonas.

Submitted by **M. ERMELINDA OLIVEIRA**, Departamento de Parasitologia, Instituto de Ciências Biológicas, Universidade do Amazonas, 69077-000 Manaus, Amazonas, Brazil (e-mail: oliveiraermelinda@hotmail.com.br), and **MARCIO MARTINS**, Departamento de Ecologia, Caixa Postal 11461, Universidade de São Paulo, 05422-970, São Paulo, Brazil (e-mail: jararaca@ib.usp.br).

BOTHROPS JARARACUSSU (Jararacussu). **SEXUAL DICHROMATISM**. Sex differences in coloration have been reported in several snake species including pitvipers (Shine 1993. *In* Seigel and Collins [eds.], Snakes: Ecology and Behavior, pp. 49–86. MacGraw-Hill, Inc. New York). For instance, adult males of the Brazilian lancehead, *Bothrops moojeni*, have less defined dorsal markings than females, and bear spotted labials, whereas the labials of females are yellow-white (Leloup1975. Acta. Zool. Pathol. Antverp. 62:173–201). Sex differences in color may also occur in juveniles. A yellow tail tip persists for 18 months from birth in males, whereas in females the yellow fades within six months (Leloup 1975, *op. cit.*). Sexual dimorphism or dichromatism is also reported for juveniles of the terciopelo, *Bothrops asper* (as *B. atrox*). Males have yellow tail tips, whereas females lack yellow tail tips (Burger and Smith 1950. Science 112:431–433).

We report herein on an additional instance of sexual dichromatism in Neotropical pitvipers. Newborns of *Bothrops jararacussu* consistently show differences related to sex in both dorsal and ventral color. Ground dorsal color of newborn males is darker (Fig. 1) and yellowish to grayish brown, whereas that of females is yellowish to pinkish brown. Moreover, the dark brown lateral markings on the body are more broken in males than in females. Like in *B. moojeni*, this feature is retained by some adult individuals (see figures in Marques et al. 2001. Serpentes da Mata Atlântica: Guia Ilustrado para a Serra do Mar, Ed. Holos, Ribeirão Preto, São Paulo. 184 pp.). The ventral side of newborn *B. jararacussu* males is yellowish to brownish gray, whereas that of females is yellowish to pinkish beige. Additionally, the chins of males bear distinct dark gray markings, whereas in females such markings are less pronounced and lighter (Fig.1). In addition to the 19 photographed newborns from a litter with no locality data, housed in the collection of the Instituto Butantan (IB), we examined 16 newborns from a litter from Cachoeirinha, Minas Gerais, southeastern Brazil (IB 8687), and 54 newborns from a litter from Curitiba, Paraná, southern Brazil (IB 26326-26394). All individuals from the three examined litters consistently showed the differences described above, which strongly indicate that dichromatism is a characteristic of newborn *B. jararacussu*. We suspect that sexual dichromatism in newborns may be present in other snake species as well, as this kind of dimorphism may be misinterpreted as individual color variation within the litter and thus would remain undetected.

We greatly thank J. Cavalheiro for calling our attention to the dichromatism of newborn *B. jararacussu* (without his keen eyes we would have only recognized individual color variation), M. Martins for fruitful discussion on the subject, and the CNPq and FAPESP for essential financial support.

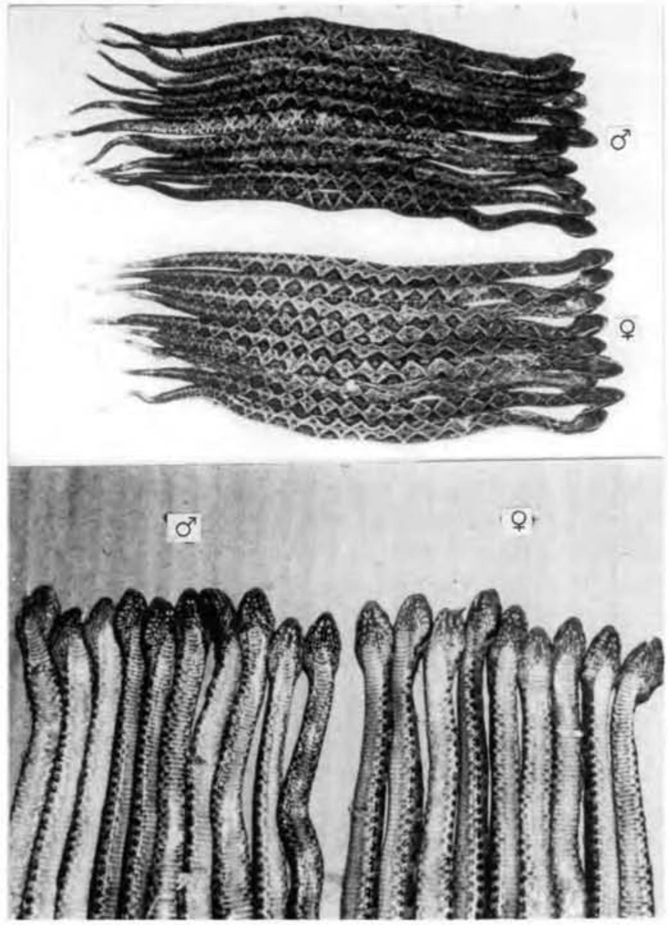

FIG. 1. A freshly-preserved newborn litter (10 males, 9 females) of *Bothrops jararacussu* showing sexual dichromatism in dorsal and ventral views.

COLUBER CONSTRICTOR CONSTRICTOR (Northern Black Racer). **WINTER ACTIVITY**. A 282 mm SVL unsexed juvenile *Coluber constrictor constrictor* was captured in a pitfall trap on 19 January 2001 in the Shenandoah Valley, 14 km S Waynesboro, Augusta Co., Virginia, USA at an elevation of 488 m. The snake was caught in an outgoing pitfall trap at an ephemeral sinkhole pond that is completely encircled by a drift fence. The juvenile was found in the pitfall trap at 0930 h when the ambient air temperature was 3°C. Pitfall traps had been checked between 1930–2100 h the previous night when ambient temperature was 1°C. Rain and snow fell intermittently throughout the night and early morning, with a total accumulation of 23 mm. Fitch (1963. Univ. Kansas Publ., Mus. Nat. Hist. 15:351–468) found that racers in Kansas were active between 15.5°C and 32.4°C and Brown and Parker (1982. *In* N.J. Scott, Jr. [ed.], Herpetological Communities, pp. 59–81. USDI Fish and Wildlife Service Report 13.) reported a range of 18.6–37.7°C in Utah. Mitchell (1994. The Reptiles of Virginia. Smithsonian Institution Press. Washington, DC.

352 pp.) reported body temperatures of 26.1–38°C for active and 19.0-35.6°C for inactive racers in Virginia. Previous extreme dates of activity for *C. constrictor* in Virginia are 22 March and 30 November, as well as an unknown date in January stemming from observation of a DOR specimen (Mitchell, *op. cit.*). Palmer and Braswell (1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill. 412 pp.) included a record of a dead juvenile racer on 6 January but did not note temperatures. The ephemeral pond from which the snake we found was exiting rose 6 cm during the night, suggesting that it may have become active in order to escape a flooded burrow or other over-wintering site. The snake appeared healthy and was capable of crawling and tongue flicking at capture. This observation represents the earliest documented record of natural activity for black racers in Virginia at the coldest ambient temperatures known for the species.

CONOPSIS LINEATA (NCN). **BROOD SIZE.** This nocturnal colubrid snake lives under rocks at high elevations in pine-oak forests and in semi-arid scrublands of south-central Mexico. Although some information about reproduction has been reported, e.g., two snakes copulating under a rock in August (Duellman 1961. Univ. Kansas Pub. Mus. Nat. Hist. 15:1–148), little is known about litter size. All species of *Conopsis* for which reproductive data are available are viviparous. *Conopsis lineata* from Hidalgo (at elevations > 2750 m) produce 2–3 embryos, and *C. lineata* from Veracruz have been reported with 3 and 5 embryos (two of the females were collected in January) (Greer 1966. Copeia 1966:371–373). A *C. lineata* from Veracruz gave birth to four offspring at the Houston Zoo during March; the neonates measured 76–79 mm TL and differed in dorsal coloration (Werler 1970. Int. Zoo. Ybk. 105–116).

On 13 April 2002, a female *C. lineata* (CIB412) measuring 233 mm total length was collected under a rock in xeric mountain scrub at 2490 m, Cerro del Zopilote, Municipality of Pachuca, Hidalgo, México. She was kept in captivity and gave birth to two young on 8 May, the latest parturition date known. Both neonates were dark with a poorly defined vertebral line. They measured 69 mm SVL (17 mm tail) and 71 mm SVL (15 mm tail) at birth. Although individuals from the same locality are known to show great variation, the two neonates reported here strongly resemble their mother in color and markings.

Submited by **IRENE GOYENECHEA**, Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo. A.P. 1-69 Plaza Juárez, Pachuca, Hidalgo, C.P: 42001, México; e-mail: ireneg@uaeh.reduaeh.mx.

***CORALLUS* SPP.** (Treeboas). **EVIDENCE OF OVER-WATER DISPERSAL.** The potential for over-water dispersal of animals via flotsam is well known (e.g., King 1962. Quart. J. Florida Acad. Sci. 25:45–52), but direct observations are rare. In the West Indies, Censky et al. (1998. Nature 395:556) reported on the arrival of iguanas (*Iguana iguana*) on Anguilla, likely hurricane-driven from Guadeloupe. Knapp (2000. Herpetol. Rev. 31:244) observed a Bahamian colubrid snake (*Alsophis vudii*) emerge from the surf on an island where the species had not before been recorded, and Henderson et al. (1995. Herpetol. Nat. Hist. 3:15–27) reported the boid snake *Boa constrictor* floating in the water between islands off the Caribbean coast of Belize.

While in Grenada in February 2002, we had a fortuitous meeting with Larry Maul at Mt. Hartman Bay, a former study site for the treeboa *Corallus grenadensis* (Henderson 2002. Neotropical Treeboas: Natural History of the *Corallus hortulanus* Complex, Krieger Publ. Co., Malabar, Florida, 197 pp.; Henderson et al. 1998. Amphibia-Reptilia 19:203–214). Mr. Maul and his wife have been sailing in the West Indies for more than a decade, with annual visits to St. Vincent and the Grenada Bank. When he learned that we had studied treeboas at the site at which we were standing, Mr. Maul immediately knew what snake we were discussing. He accurately described the appearance of *Corallus* and its defensive behavior. Mr. Maul then proceeded to describe two encounters he had with seagoing treeboas off St. Vincent and Bequia. Both episodes occurred in June–July 2001, during mid- to late-afternoon, and in very flat, calm water. Both treeboas were swimming and neither was associated with a mat of vegetation or other flotsam.

One treeboa was encountered swimming ca. 1.5–2.0 km off Chateaubelair, St. David Parish, St. Vincent. At that distance it would have been beyond Chateaubelair Island, and probably out of Chateaubelair Bay. The Mauls rescued the snake and released it near Chateaubelair. Mr. Maul described the snake as appearing "exhausted" but that it recovered quickly and made attempts to bite. Almost certainly the snake was the St. Vincent endemic *Corallus cookii* (rather than the Grenada Bank endemic *C. grenadensis*). To the north, the nearest major land mass is St. Lucia, ca. 60 km from Chateaubelair. Without supporting flotsam, a successful landfall would appear unlikely.

A second treeboa was found swimming ca. 3.5 km off Bequia, in the Bequia Channel between Bequia and St. Vincent. It was off Port Elizabeth and out of Admiralty Bay. The distance from Admiralty Bay to the southern tip of St. Vincent is ca. 15.0 km, with the current pushing from St. Vincent towards Bequia (Doyle 1994. Sailors Guide to the Windward Islands, Chris Doyle Publ., St. Vincent, W.I. 334 pp.). The snake probably originated from either St. Vincent (*Corallus cookii*) or from Bequia (*C. grenadensis*). Again, the Mauls rescued the snake and deposited it on vegetation on Bequia. If it was a *C. cookii* moving south towards Bequia, a successful landfall might have been possible. If the snake was *C. grenadensis*, without supporting flotsam the liklihood of reaching St. Vincent was probably remote.

That the Mauls encountered two treeboas over a relatively short span of time is intriguing, and one wonders how often treeboas (as well as other snakes) are set adrift for whatever reason. At our Mt. Hartman Bay study site on Grenada, *Corallus grenadensis* was often encountered in coastal mangroves (*Rhizophora mangle*), both on the land and sea sides, and treeboas commonly slept by day and foraged by night on vegetation over water (Henderson et al.1998, *op. cit.*). Similarly, by day *C. grenadensis* was observed resting in a mangrove tree completely surrounded by water at Lower Woburn (St. George Parish; Henderson, *op. cit.*). That treeboas occasionally fall into the water would not be a surprise,

and at certain times they may not be able to reach land before being carried out to sea on a prevailing current. Most such episodes probably end with the death of the snake from dehydration, drowning, or predation.

Corallus almost certainly reached the West Indies by over-water dispersal via the Guiana Current from northeastern South America during the Quaternary (Hedges 1996. *In* Powell and Henderson [eds.], Contributions to West Indian Herpetology: A Tribute to Albert Schwartz, pp. 95–127. SSAR Contrib. Herpetol. 12, Ithaca, New York; Hedges 2002. *In* Zanoni [ed.], Flora of the Greater Antilles, New York Bot. Garden, *in press*). A dispersal event of that magnitude surely required a mat of vegetation on which snakes could rest and avoid dehydration, overheating, drowning, and predation. Even under the best of conditions, most reptiles would succumb before reaching a new landfall. Although the possibility exists that the seagoing treeboas encountered by the Mauls represented mainland species (e.g., *C. hortulanus* or *C. ruschenbergerii*), based on the absence of flotsam and the near geographic presence of the West Indian taxa, that potential seems highly unlikely.

We thank Larry Maul, skipper of the Lord Nelson Cutter "Shalom" for realizing this information might be of interest to biologists, and for his enthusiastic willingness to share it with us. Henderson's field expenses were provided by the J. C. Penny Golden Rule Foundation (via Robert W. Bourgeois), the Milwaukee Public Museum, the Windway Foundation, and Paul Bourgeois. Robert Powell made numerous suggestions to improve the clarity of the paper.

CROTALUS CERASTES (Sidewinder). **PREY/PREDATOR WEIGHT-RATIO.** A key innovation in the evolutionary history of snakes is the ability to ingest large prey items. Vipers are especially renowned for this ability, perhaps aided by the predigestive function of venoms. The largest prey/predator weight-ratio previously recorded was from a neonate viper, *Bothrops atrox*; this snake ingested a *Cnemidophorus* lizard, resulting in a relative prey/predator weight-ratio of 1.56 (Greene 1983. Amer. Zool. 23:431–441). Despite the presumed dietary advantages of such large meals, the size of a meal can render snakes vulnerable to predation (e.g., Pauly and Benard 2002. Herpetol. Rev. 33:56–57). Here we report the largest relative prey item recorded from snakes, which may have contributed to the snake's death. A dead neonate *C. cerastes* was found on a lightly traveled road near the Ranger Station at the Ocotillo Wells State Vehicular Recreational Area, San Diego Co., California, USA, 80 m elev. (N33°9.31', W116°8.98'). Approximately 6 cm of the tail of a *Cnemidophorus tigris* was protruding from its mouth, and the remainder of the lizard formed an obvious bolus. The snake was not visibly damaged in any way, but was slightly decomposed and desiccated prior to preservation. The SVL of the preserved snake is 229 mm, the SVL of the lizard is 73.5 mm, plus a tail length of 196 mm. Dissection revealed that the head of the lizard was located at the level of the lower intestine. The relative prey mass of this food item was 1.72. Dissection revealed dipteran insect larvae (maggots) in both the coelom of the snake and the head of the lizard. It is uncertain if the maggots originated from the snake, or if the snake ingested the lizard as carrion containing maggots. We cannot rule out the possibility that the snake was killed by an automobile, but we observed no apparent vehicle-associated trauma on the specimen. Although the exact cause of death is uncertain, the snake may have been physically incapacitated by the meal it ingested and died of exposure to daytime temperatures—if not as a result of ingesting the meal itself. The snake and the prey item were deposited at the Collection of Vertebrates, University of Texas, Arlington, Texas (UTA R-51519). We thank Harry Greene for insightful discussion on this topic.

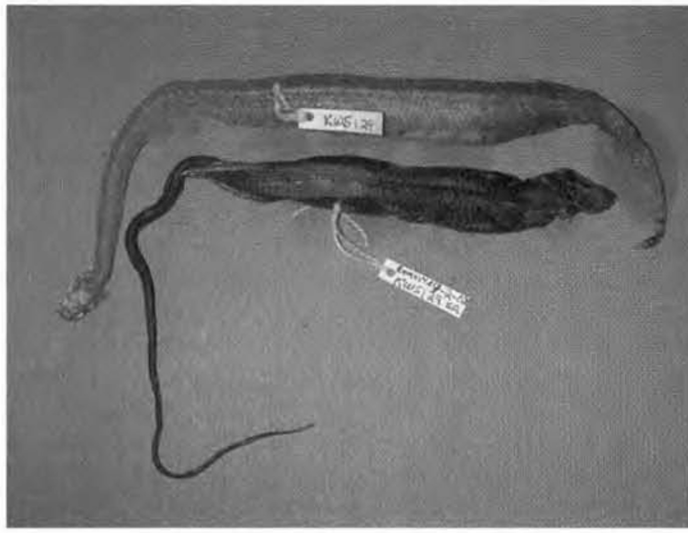

FIG. 1. A neonate *Crotalus cerastes* and the prey item (*Cnemidophorus tigris*) it had consumed; the relative predator/prey mass of this food item was 1.72.

SETSER**, Department of Biology, Utah State University, Logan, Utah 84322-5305, USA (e-mail: dmulcahy@biology.usu.edu), and **ERIC HOLLENBECK,** California Department of Parks and Recreation, Ocotillo Wells District, 5172 Hwy 78, Borrego Springs, California 92004, USA.

CROTALUS ENYO (Baja California Rattlesnake). **ENDOPARASITES.** The biology of *Crotalus enyo* was summarized by Beaman and Grismer (1994. Cat. Amer. Amphib. Rept. 589:1–6). There are no reports of endoparasites for this species. The purpose of this note is to report the presence of larvae (tetrathyridium) of tapeworms (Cestoda) and larvae (cystacanth) of spiny-headed worms (Acanthocephala) in *C. enyo*. The body cavities of 52 *C. enyo* (19 from Baja California and 33 from Baja California Sur, Mexico) from the herpetology collections of the California Academy of Sciences (CAS), Natural History Museum of Los Angeles County (LACM), and San Diego Society of Natural History, (SDSNH) were examined for helminths. A mid-ventral incision was made in the body wall, and organ surfaces and mesenteries in the posterior portion of the body cavity were visually examined. Oblong whitish bodies, ca 1 x 3 mm, were found in two snakes

from Baja California Sur which proved upon microscopic examination to be tetrathyridia (larvae) of *Mesocestoides* sp. (CAS 143982) and oligacanthorhynchid acanthocephalan cystacanths (larvae) (CAS 15632). Prevalence of infection (infected snakes/snakes sampled x 100) was 2% for each parasite species. Selected specimens were deposited in the U.S. National Parasite Collection (USNPC), Beltsville, Maryland: acanthocephalan cystacanths USNPC 92196; tetrathyridia of *Mesocestoides* sp. USNPC 92197.

The occurrences of *Mesocestoides* sp. and oligacanthorhynchid cystacanths in North American rattlesnakes have been summarized in Goldberg and Bursey (2000. Herpetol. Rev. 31:104). Rattlesnakes may serve as paratenic (transport) hosts for tetrathyridia of *Mesocestoides* sp. (Bolette 1997a. J. Parasitol. 83:751–752) and cystacanths of oligacanthorhynchid acanthocephalans (Bolette 1997b. Southwest. Nat. 42:232–236). *Crotalus enyo* represents a new host record and Baja California Sur a new locality record for both tetrathyridia of *Mesocestoides* sp. and cystacanths of oligacanthorhynchid acanthocephalans.

We thank B. Hollingsworth (SDSNH), D. Kizirian (LACM), and J. Vindum (CAS) for permission to examine specimens.

CROTALUS MITCHELLII (Speckled Rattlesnake). **MATING**. Most North American pitvipers have a distinct fall and/or spring mating season, exhibiting the aestival postnuptial pattern of the male reproductive cycle (Saint Girons 1982. Herpetologica 38:5–16). Recent evidence suggests that *C. mitchellii* males undergo spermiogenesis primarily in the spring (Goldberg 2000. Bull. South. California Acad. Sci. 2:101–104) in contrast to other North American rattlesnakes (e.g., Aldridge 1979. J. Herpetol. 13:187–192; Goldberg 1999. Western North Am. Nat. 60:98–100; Jacob et al. 1987. Southwest. Nat. 33:273–276). However, few mating dates for wild *C. mitchellii* have been published. Here we present our own observations as well as those from the literature in order to elucidate when mating occurs in *C. mitchellii* under natural conditions.

On the afternoon of 18 April 1953, a mating pair of *C. mitchellii* was reported by Brattstrom (Brattstrom 1965. Amer. Midl. Nat. 73:376–422.) near Afton, San Bernardino County, California, USA. On 18 April 1980, T. B. Johnson photographed (see Fig. 13 in Lowe et al. 1986. The Venomous Reptiles of Arizona, Arizona Game and Fish Department, Phoenix. p. 115) a pair of mating *C. mitchellii* in the Mohawk Mountains, Yuma County, Arizona, USA. The pair (T. B. Johnson pers. comm.) was courting at 0908 h and mated at 0935 h. The female retreated to the rocks at 1118 h as ambient temperatures increased. The male, with hemipenis still inserted, was dragged along with the female. On 11 June 1964 at 1800 h, G. Ahern found a pair of *C. mitchellii* copulating on the western slope of the San Jacinto Mountains, Riverside County, California, USA (Goldberg 2000, *op. cit.*). At 2248 h on 13 June 1995 (air temperature ca. 29°C, sunny substrate temperature ca. 40°C) RSR found a copulating pair of *C. mitchellii* in the shade of a small bush near an unmarked jeep trail, 2 km SW of the junction of Hwy 247 and Mikisha Blvd., San Bernardino Co., California, USA (34°19'25.6"N, 116° 30' 26.1"W). Rattling by the larger male drew attention to their presence. The male assumed a defensive posture, but remained engaged with the female while photographs were taken. At 2300 h on 23 May 2000 (air temperature ca. 26°C with the asphalt significantly warmer) GEAG discovered a female *C. mitchellii* crossing Kelbaker Rd., north 5 km from the junction of Hwy 40 and Kelbaker Rd., Mojave Natl. Preserve, San Bernardino Co., California, USA (34°44'00"N, 115°40'00"W). A male was 2 m away, crawling rectilinearly towards the female (identification confirmed by H. W. Greene from photographs). Both snakes were briefly restrained in plastic acrylic tubes, sexed, and then released 5 m off the road. Upon release, the male immediately pursued, courted, and mated with the female (hemipenal insertion was noted). Mating continued for more than 30 min., at which time the pair was left alone. GEAG found another two *C. mitchellii*, presumably a courting pair, on the same evening (23 May 2000) 100 m to the south. Both animals were lifted from the road with hooks; no courtship or mating was observed.

During a field study (by RSR) from 1998 to 1999 in Johnson Valley, San Bernardino Co., California, USA, three large male *C. mitchellii* were encountered crossing roads in June. These snakes were many kilometers from rocky retreats, apparently traversing long distances through creosote (*Larea tridentata*) flats. Long distance movements by large adults through atypical habitat are most consistent with mate searching and, despite daily road driving from May to October, no other *C. mitchellii* were encountered away from rocky habitats. RSR collected a post-ovulatory gravid female on 3 August 1998 in the western foothills of Rodman Mountain (34°39'34"N, 116°39'34"W). Mucous removed from her reproductive tract by oviductal lavage was examined microscopically and contained abundant active sperm, suggesting a recent mating.

These data indicate a primarily spring and summer mating season for *C. mitchellii*, with an extension of mating activity up to the time of ovulation (Goldberg 2000, *op. cit.*; RSR, pers. obs.) in June. Goldberg's histological data suggest that mating could occur throughout the month of June. Mating in close temporal proximity to ovulation might reduce reliance on long-term sperm storage (e.g., Schuett 1986. Copeia 1986:807–811), perhaps biasing multiple paternity through an order effect that depends on shear numbers of sperm present rather than on sperm selection by females.

We thank Akito Y. Kawahara and A. Kristopher Lappin for their contributions to this fieldwork.

REISERER**, Museum of Vertebrate Zoology, Department of Integrative Biology, University of California, Berkeley, California 94720, USA (e-mail: cerastes@uclink4.berkeley.edu).

CROTALUS PRICEI MIQUIHUANUS (Miquihuanan Rattlesnake). **DIET**. Few prey items have been reported for the montane rattlesnake species *Crotalus pricei*. Klauber (1972. Rattle-

snakes: Their Habits, Life Histories, and Influence on Mankind. 2nd ed. Univ. California Press, Berkeley, California. 1533 pp.) reported a field mouse and *Sceloporus jarrovii jarrovii* as prey items of *Crotalus pricei pricei*. Armstrong and Murphy (1979. The Natural History of Mexican Rattlesnakes. Univ. Kansas Mus. Nat. Hist. Special Publ. 5:1–88) found a juvenile *Sceloporus poinsettii* in an adult *C. p. pricei*. Little published data exist on the natural history of the endemic Mexican subspecies *C. p. miquihuanus* and no prey items have been recorded for this subspecies. Armstrong and Murphy (*op. cit.*) stated that lizards of the genus *Sceloporus* appear to be the main prey of *C. p. miquihuanus*.

On 29 May 2001 we collected an adult male *C. p. miquihuanus* near Santa Rita, Municipio Arteaga, Coahuila, México, in thick agave (*Agave* spp.) and scrub oak (*Quercus* sp.) among exposed limestone. The specimen had a noticeable mid-body bulge. Seven days later the specimen defecated. Analysis of the fecal matter revealed scales and a partially digested front leg of a *Barisia imbricata ciliaris*. Several specimens of this anguid were found in the same general area as the specimen of *C. p. miquihuanus*.

We thank James R. Dixon for his help.

Submitted by **ROBERT W. BRYSON, JR.**, Department of Biology, Sul Ross State University, Alpine, Texas 79832, USA, **JAVIER BANDA**, and **DAVID LAZCANO**, Laboratorio de Herpetología, Universidad Autónoma de Nuevo León, Apartado Postal - 513, San Nicolas de los Garza, Nuevo León, C.P. 66450, México.

ELAPHE O. OBSOLETA (Black Ratsnake) **ESCAPE BEHAVIOR, HABITAT**. *Elaphe o. obsoleta* is a terrestrial species with arboreal foraging tendencies (Fitch 1999. A Kansas Snake Community: Composition and Changes Over 50 Years. Krieger Publishing, Malabar, Florida. xi + 165 pp.). Weatherhead and Hoysak (1989. Can. J. Zool. 67:463–468) indicated that in June, males are often wide-ranging and are found in open areas, and Stickel et al. (Amer. Midl. Nat. 103:1–14) reported that individual snakes included a mixture of habitats within their ranges. None of these studies mentioned aquatic behavior in this species.

On 27 May 2002 at 1630 h, while seeking *Nerodia sipedon* in the "400 ponds" enclosure of the Nelson Environmental Study Area [University of Kansas Field Station and Ecological Reserves (KSR)], pond 437 (NE1/4, Section 33, TWP11S RNG20E, Jefferson County, Kansas), I observed a ca 1 m TL *E. o. obsoleta* swimming diagonally across the 20.6 m x 20.6 m pond. The 6.7-ha site of these ponds is not far from wooded habitat and is surrounded by open areas; the enclosure containing these ponds is not wooded and is mowed regularly. The snake's head was elevated ca. 50 mm above the water surface. It swam directly to a small, emergent willow (*Salix* sp.) directly in front of my observation point and ca 2.5 m from shore, climbed into the lowermost branches, and remained still while stretched out on a thin, horizontal branch. The snake seemed unaware of a small bird nest (species unknown) of apparently recent construction, and also was unaware of me. Air temperature was 27°C, no cloud cover, no breeze.

After 15 minutes of observation, I attempted capture of the snake. As the pond bank dropped steeply away and the snake was just beyond effective reach of my tongs, I tossed a twig just beyond it in the hope that it would swim to shore not far from my vantage point. Instead, it dropped into the water, dove, and from the resultant bubble trail from disturbed vegetation swam ca 10 m into the pond, then turned towards the adjacent bank where I saw it emerge. I subsequently lost track of it in vegetation.

Fitch (pers. comm.) indicated that never in 50+ years of observing this species in the area had he seen one utilize an aquatic habitat in this fashion. Of the many specimens I have observed in the area since 1970, none has been in an aquatic habitat. However, Fitch (Copeia 1963:649–658) noted that on the University of Kansas Fitch Natural History Reservation the species is "present in all habitats," and also presented tentative evidence that some individuals include frogs in their diet.

Sincere thanks are expressed to Galen Pittman (KSR Station Manager/Biologist) for ongoing logistic support with my research on the properties.

Submitted by **GEORGE R. PISANI**, University of Kansas Field Station and Ecological Reserves, 350 Wild Horse Road, Lawrence, Kansas 66044, USA; e-mail: gpisani@ku.edu.

ELAPHE OBSOLETA QUADRIVITTATA (Yellow Ratsnake). **ATTEMPTED PREDATION**. During mid-morning on 24 March 2000, we observed a red-shouldered hawk (*Buteo lineatus*) attack an *Elaphe obsoleta quadrivittata* in Corkscrew Swamp Sanctuary near Immokalee, Florida, USA. The hawk landed on a horizontal branch of a large cypress (*Taxodium distichum*) tree near the top of the canopy (~15 m) in a primary stand of cypresses. It seized a large yellow rat snake, and a struggle ensued for ca. 20 sec. After that time, the snake disappeared from view, and the hawk appeared confused. The hawk remained on the branch for another minute, and then departed with nothing in its beak or talons. The snake apparently escaped predation, though we were unable to ascertain its whereabouts following the attack.

During the attack, a large shed skin was knocked off the branch and dangled into our view. We estimated the length of the visible portion as approximately 1 m. This strongly suggests that the snake was shedding its skin while resting on a branch near the top of the forest canopy. We are not aware of any other records of arboreal shedding in *E. o. quadrivittata*, but apparently it is common in *E. o. obsoleta* (Stickel et al. 1980. Amer. Midl. Nat. 103:1–14). Our observation suggests that shedding may increase a snake's visibility to aerial predators or reduce its ability to flee quickly.

We thank R. Root and P. Marks for organizing the trip to Corkscrew Swamp Sanctuary, Cornell University for support of the EEB field course, and H. Greene and P. Marks for helpful comments on this note.

Submitted by **PETER B. McINTYRE, ERIK DOPMAN**, and **SEAN MULLEN**, Department of Ecology and Evolutionary Biology, Corson Hall, Cornell University, Ithaca, New York 14853-2701, USA; e-mail (PBM): pbm3@cornell.edu.

ELAPHE QUADRIVIRGATA (Japanese Striped Snake). **PREDATION.** On 29 August 2000 at ca. 1900 h, I caught a largemouth bass (*Micropterus salmoides*) (142 mm SL, 173 mm TL) while fishing in an irrigation pond in Higashi-Hiroshima,

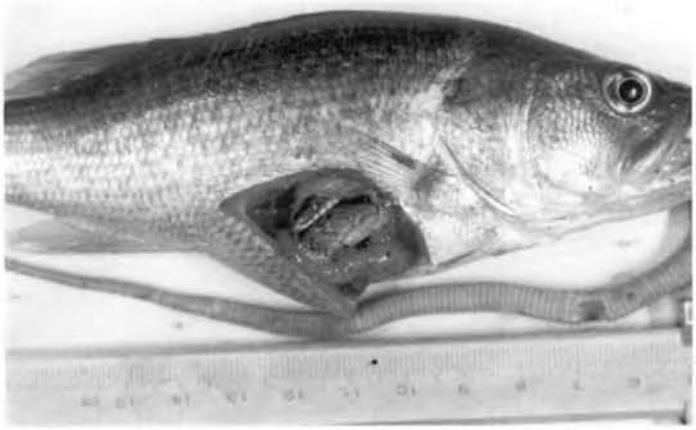

FIG. 1. *Elaphe quadrivirgata* in the stomach of *Micropterus salmoides*.

Hiroshima Prefecture, Japan (34°24'N, 132°43'E, 240 m elev.). I inserted my finger into the fish's mouth to search for stomach contents because the fish had a swollen abdomen. I found the tail of a snake by this process. Upon dissection, I removed a juvenile *Elaphe quadrivirgata* (259 mm SVL, 327 mm TL) (Fig. 1) and a spider (ca. 6 mm TL). This is the first report of predation on a snake by the introduced *M. salmoides* in Japan (Tanaka and Mori 2000. Current Herpetol. 19:97–111).

Submitted by **JUNSUKE MARUNOUCHI**, Laboratory for Amphibian Biology, Graduate School of Science, Hiroshima University, Kagamiyama 1-3-1, Higashi-Hiroshima 739-8526, Japan.

ELAPHE VULPINA (Fox Snake). **REPRODUCTION.** Few data are available on the reproductive biology of fox snakes in agricultural regions of the Midwestern U.S. On 16 June 1998, we found a gravid 81.3 cm SVL fox snake under a 1-mm thick 45 cm x 75 cm piece of black rubber in a grassy field at the Middle Fork Fish and Wildlife Area, Vermilion County, Illinois, USA. The fox snake was taken to the laboratory where, on 29 June, 17 eggs were deposited. The eggs were incubated on vermiculite in a ventilated container sitting in a water bath of 28.1°C. On 12 Aug, after 44 days of incubation, all eggs hatched. The hatchlings were released near the site of the mother's capture. According to Ernst and Barbour (1989. Snakes of Eastern North America, George Mason University Press, Fairfax, Virginia. 282 pp.), "mating occurs in early June and July" for fox snakes, and eggs are deposited 30 days later. These authors cite clutch sizes from 7–27, with 15–20 eggs being usual, and the size of the fox snake clutch described herein is within this range. However, gestation for species of *Elaphe* usually takes closer to 45 days at ca. 27–28°C in the laboratory (WLK, pers. obs.). This, coupled with the fact that this fox snake was quite distended when collected on 16 June, suggests that fox snakes in Illinois may start to breed as early as mid-May.

LAWRENCE KELLER**, Department of Natural Resources and Environmental Sciences, University of Illinois Urbana-Champaign, Urbana, Illinois 61801, USA (e-mail: w-keller@uiuc.edu), and **EDWARD J. HESKE**, Illinois Natural History Survey, 607 East Peabody Drive, Champaign, Illinois 61820, USA.

ENHYDRIS PLUMBEA (Olive Water Snake). **DIET**. Although *Enhydris plumbea* is often reported to feed on amphibians (adults and larvae) and fishes, documented specific predation records from the wild are rare. The stomach of an adult *E. plumbea* (IRSNB 15588; SVL 337 mm) collected at "25 km nordwestlich von Lan-Sak, 65 km nordwestlich von Uthai-Thani, ca 220 km nordwestlich von Bangkok, Thailand, 110 m über 00," in Uthai Thani Province, contained a partly digested *Macrognathus siamensis* (Mastacembeliformes: Mastacembelidae) ingested head first. This fish species was previously recorded from Uthai Thani Province (Monkolprasit et al. 1997. Checklist of Fishes in Thailand. Office of Environmental Policy and Planning, Biodiversity Series 4:1–353). This fish lives in slow-moving or standing waters and begins its foraging activity at dusk (Rainboth 1996. Fishes of the Cambodian Mekong. FAO Species Identification Field Guide for Fishery Purposes, Food and Agriculture Organization of the United Nations, Rome. 265 pp.), similar to *E. plumbea*.

Submitted by **OLIVIER S. G. PAUWELS** (e-mail: osgpauwels@hotmail.com), and **GEORGES LENGLET** (e-mail: Georges.Lenglet@sciencesnaturelles.be), Department of Recent Vertebrates, Institut Royal des Sciences naturelles de Belgique, Rue Vautier 29, 1000 Brussels, Belgium.

GYALOPION QUADRANGULARE (Thornscrub Hook-nosed Snake). **REPRODUCTION.** The thornscrub hook-nosed snake, *Gyalopion quadrangulare,* occurs from extreme southern Arizona, USA, south to Nayarit, Mexico (Stebbins. 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, Boston. 336 pp.). Virtually nothing is known about reproduction of this snake other than that it is oviparous (Bartlett and Tennant. 2000. Snakes of North America Western Region. Gulf Publishing Company, Houston, Texas. 312 pp.). The purpose of this note is to report on an examination of *G. quadrangulare* gonads from Mexico from the herpetology collections of the Natural History Museum of Los Angeles County, Los Angeles (LACM) and The University of Arizona, Tucson (UAZ) and to provide the first information on the reproductive cycle of this species.

Fifteen *G. quadrangulare,* 7 males, mean snout-vent length, SVL = 207 mm ± 26 SD, range = 183–207 mm; 8 females, mean SVL = 234 mm ± 33 SD, range = 183–266 mm were examined. Snakes were collected 1960–1983. The left gonad was removed, dehydrated in alcohol and embedded in paraffin. Histological sections were cut at 5 μm and stained in Harris' hematoxylin followed by eosin counterstain from all snakes except those females that contained enlarged follicles or oviductal eggs.

Females contained enlarged follicles > 9 mm length or oviductal eggs from early June to mid-August. One 12 June female (LACM 38506, SVL = 205 mm) from Sinaloa, Mexico contained 4 oviductal eggs; another collected 22–23 June (LACM 65187, SVL = 257 mm) from Sonora, Mexico contained 4 enlarged follicles. One collected 3 July (LACM 6835, SVL = 183 mm) from Sinaloa, Mexico contained 3 enlarged follicles; another collected 12 July (LACM 127815, SVL = 266 mm) from Sonora, Mexico contained 5 oviductal eggs; another collected 30 July (UAZ 39233, SVL = 215 mm) from Sinaloa, Mexico was not reproductively active. One collected 6 August (LACM 38499, SVL 264 mm) from Sonora, Mexico contained three enlarged follicles; another col-

lected 8 August (UAZ 45197, SVL = 265 mm) from Sonora, Mexico contained three oviductal eggs; another collected 17 August (LACM 50779, SVL = 220 mm) from Sonora, Mexico was not reproductively active. Mean clutch size (N = 6) was 3.7 ± 0.82 SD, range = 3–5.

Spermiogenesis was in progress in the following males: 4 June (LACM 136922, SVL = 209 mm) Nayarit, Mexico; 6 June (LACM 38181, SVL = 257 mm) Sinaloa, Mexico; 30 June (LACM 38511, SVL = 183 mm) Sinaloa, Mexico; 19 July (LACM 38509, SVL = 198 mm) Sinaloa, Mexico; 17 August (UAZ 36446, SVL = 190 mm) Sonora, Mexico; 23 August (LACM 6851, SVL = 203 mm) Sinaloa, Mexico. One 7 September male (LACM 121330, SVL = 206 mm) from Sinaloa, Mexico was in late spermiogenesis. Germinal epithelium was reduced to a few layers, there were small clusters of metamorphosing spermatids and small amounts of sperm.

In view of the presence of females with enlarged follicles or oviductal eggs from June to August and males in spermiogenesis from June to September, it appears *G. quadrangulare* has an extended reproductive season that encompasses both spring and summer.

I thank David A. Kizirian (Natural History Museum of Los Angeles County) and Charles H. Lowe (University of Arizona) for permission to examine *G. quadrangulare*.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA.

HELICOPS ANGULATUS (Water-Snake). **DIET**. On 05 June 2001 we collected one specimen of *Helicops angulatus* (Centro de Estudos e Pesquisas Biológicas - CEPB 4495, male SVL 440 mm; body weight 28 g), on the left bank (SW) of Piranhas River, Municipality of Piranhas, Southwestern region of the State of Goiás, Brazil (16°35'22"S, 51°47'41"W). The snake was eating a female *Hyla crepitans* (SVL 43.8 mm).

Among South American herpetofaunal studies there is no mention of the biology and life history of *H. angulatus*. The known data about its biology suggests that this species feeds on tadpoles, frogs, and lizards, but especially fishes (Dixon and Soini 1986. The Reptiles of Upper Amazon Basin, Iquitos Region, Peru. Milwaukee Publ. Mus. 154 pp.; Duellman 1978. Misc. Publ. Mus. Nat. Hist. Univ. Kansas 65:1–352).

Our observation is interesting because *H. angulatus* is a semiaquatic snake and the prey item is an arboreal frog. This is the first natural history report of this taxon in central Brazil, and it adds to the knowledge of the biology of this widespread species in South America (Roze 1966. La Taxonomia y Zoogeografia de los Ofidios de Venezuela, Edit. Biblioteca, Caracas. 362 pp.; Pérez-Santos and Moreno 1988. Serpientes de Colombia, Monog. VII, Mus. Reg. Sci. Nat. Torino. 517 pp.; Pérez-Santos and Moreno 1991. Serpientes de Ecuador, Monog. XI, Mus. Reg. Sci. Nat. Torino. 538 pp.).

Submitted by **NELSON JORGE DA SILVA JR., IVAN FRANÇA E SOUZA, WILIAN VAZ SILVA, RAFAEL SILVEIRA RIBEIRO, MÁRCIO CANDIDO DA COSTA, NILTON CARLOS DO VALLE,** and **HÉLDER LÚCIO RODRIGUES SILVA**, Laboratório de Herpetologia, Centro de Estudos e Pesquisas Biológicas, Universidade Católica de Goiás, Ave. Universitária, 1440, Setor Universitário, 74.210-010, Goiânia, Goiás, Brazil (e-mail [NJS]: njs@ucg.br).

LEPTOPHIS AHAETULLA MARGINATUS (Southern Green Parrot-Snake). **DIET**. *Leptophis ahaetulla marginatus* is an arboreal snake with a maximun total length of 1500 mm (Cei 1993. Reptiles del Noroeste, Noreste y Este de Argentina. Herpetofauna de las Selvas subtropicales, Puna y Pampas. Mus. Reg. Sc. Nat. Torino, Monogr. 14:575). It occurs from southeastern Bolivia to western São Paulo State in Brazil, through Paraguay and southern Brazil to northeastern Argentina and Uruguay (Peters and Orejas Miranda 1970. Catalogue of Neotropical Squamata: Part I. Snakes. U.S. Nat. Mus. Bull. 297:163). The diet of *L. ahaetulla* consists primarily of arboreal or semiarboreal hylid frogs, and secondarily of bird eggs, young birds, and lizards (Oliver 1948. Bull. Amer. Mus. Nat. Hist. 92; Duellman 1978. The Biology of an Equatorial Herpetofauna in Amazonian Ecuador. Misc. Publ. Univ. Kansas Mus. Nat. Hist. 65; Cunha and Nascimento 1993. Publ. Avul. Mus. Paraense E. Goeldi, Zool. 107). Limited data pertaining to *L. a. marginatus* suggest that it feeds mainly on hylid frogs and lizards (Achaval and Olmos 1997. Anfibios y Reptiles de Uruguay. Barreiro y Ramos S.A., Montevideo, Uruguay; Yanosky et al. 1996. Herpetol. Nat. Hist. 4:97–109).

We examined 21 specimens of *Leptophis ahaetulla marginatus* (SVL range = 560–967 mm) from Corrientes, Formosa, Misiones, and Santa Fe provinces (Argentina) deposited in the following collections: Instituto Nacional de Limnología, Consejo Nacional de Investigaciones Científicas y Técnicas, Santa Fe (INALI, 14 specimens); Félix de Azara collection, now deposited in the Museo Argentino de Ciencias Naturales, Buenos Aires (MACN, 3 specimens); Centro de Investigaciones Ecológicas Subtropicales, Parque Nacional Iguazú, Misiones (CIES, 3 specimens) Museo Provincial de Ciencias Naturales Florentino Ameghino, Santa Fe (MFA, 1 specimen). Museum numbers for material examined are available from the author upon request. Prey items were deposited in the Instituto Nacional de Limnología (INALI).

Eleven *Leptophis ahaetulla marginatus*, 52.4% of the specimens examined, contained recoverable food items. Of 16 prey

TABLE 1. Prey eaten by *Leptophis ahaetulla marginatus* based on examination of stomach contents of preserved specimens.

Prey taxon	Prey frequency	% of total prey items
Amphibians		
Hyla nana	1	6.25
Scinax sp.	3	18.75
Scinax aff. *acuminata*	2	12.50
Scinax nasica	3	18.75
unidentified Hylidae	1	6.25
unidentified amphibians	1	6.25
Birds		
Zonotrichia capensis	1	6.25
Coryphospingus cucullatus	1	6.25
unidentified bird eggs	2	12.50
unidentified vertebrate	1	6.25

items found, 11 (68.8%) were amphibians, 2 (12.5%) were young birds, 2 (12.5%) were birds' eggs, and 1 (6.3%) was an unidentified vertebrate (Table 1). The two young birds were attacked in the nest in a tree during the morning (and another snake was observed pursuing a frog in a tree at 1600 h (ARG, pers. obs.). Six snakes were observed active between 1100 h and 1740 h, most of them in trees or bushes. These observations and the prey items recovered (Table 1), confirm that this subspecies is diurnal and is an active forager in trees or bushes as suggested by Oliver (1948, *op. cit.*).

We acknowledge the curators of the museums mentioned for allowing us to examine the material in their care, Marcos Di Bernardo for bibliographic data, and the CONICET (Concejo Nacional de Investigaciones Científicas y Técnicas) for support of our investigations.

LIOPHIS JAEGERI (Jaeger's Ground Snake). **DIET.** *Liophis jaegeri* is a small colubrid occurring in Brazil, Bolivia, Paraguay, Argentina, and Uruguay. This snake lives in humid and aquatic habitats where it mainly feeds on amphibians. After a heavy rainfall on 7 January 2001 at 2130 h, we observed a juvenile *L. jaegeri* (226 mm SVL; 277 mm total length; 7.72 g mass) at a small pond in the CPCN Pró-Mata reserve, municipality of São Francisco de Paula, Rio Grande do Sul, southern Brazil (960 m elevation). The snake's head was inside a small hole in the mud and its tail was slowly moving. After being caught, the snake regurgitated white foam and 11 tadpoles at Gosner stage 19. Inside the hole, we found a foam nest of the leptodactylid *Leptodactylus plaumanni* containing tadpoles of the same stage. To our knowledge, this is the first record of a snake feeding on a subterranean anuran foam nest. To verify our observation, this snake and four other *L. jaegeri* from the same area (two adult females, one adult male, and one juvenile) were kept together inside a terrarium. For one week the snakes were only provided with water, then we offered a new-built foam nest of *L. plaumanni*. The specimen found eating in the hole under natural conditions immediately approached the nest and began to feed on eggs by totally immersing its head in the foam. After 2 min. another snake started eating, and after 10 min. all five snakes were feeding on the nest. These observations confirm that the diet of *L. jaegeri* comprises anuran eggs and tadpoles from foam nests.

We thank Marcos Di-Bernardo for his cooperation.

Submitted by **MIRCO SOLÉ**, Zoologisches Institut, Universität Tübingen, Auf der Morgenstelle 28, D-72076 Tübingen, Germany (e-mail: mirco.sole@uni-tuebingen.de), and **AXEL KWET**, Zoologie, Staatliches Museum für Naturkunde Stuttgart, Rosenstein 1, D-70191 Stuttgart, Germany (e-mail: axel.kwet@uni-tuebingen.de).

LIOPHIS MARYELLENAE (Cobra-d'água). **DIET**. The colubrid snake *Liophis maryellenae* is reported from the tablelands of central and southeastern Brazil (Dixon 1985. Proc. Biol. Soc. Washington 98:301; Dixon 1989. Smithsonian Herpetol. Information Serv. 79:15). Snakes of the genus *Liophis* are primarily terrestrial but some species are semiaquatic or semifossorial, being found near several types of water bodies, including swamps, streams and ponds associated with forests and grasslands (Dixon 1980. Contrib. Biol. Geol. 31:1–40). Species of *Liophis* are known to feed mainly on arthropods, earthworms, fishes, salamanders, adult and larval anurans, lizards and birds (Dixon, *op. cit.*); however, no diet information has been reported from *L. maryellenae*. Herein we report on gut contents of one individual found in the wild.

On 15 February 1999, in the afternoon, JC found an adult male (SVL = 370 mm, tail length = 125 mm) resting in the standing water of a stream at the Parque Nacional da Serra do Cipó, Minas Gerais State, Southeastern Brazil (19°12'–19°20'S, 43°30'–43°40'W). Upon capture it regurgitated one partially digested *Hyla* tadpole. The tadpole was probably *H. saxicola* (Hylidae) because a large number were present in the stream at the time of the capture. The snake and the tadpole are deposited in the herpetological collection of the Universidade Federal de Minas Gerais (UFMG-218), Brazil. Estimated prey/predator mass ratio was 0.0024.

We thank Vinícius Xavier and Claudia M. Jacobi for comments and improvements on this manuscript.

LIOPHIS POECILOGYRUS (Trash-snake). **DIET**. On 18 November 1999 and 16 June 2001 we collected two specimens of *Liophis poecilogyrus*, at Cana Brava region, on the left bank (W) of Tocantins River, Municipality of Minaçu, northern State of Goiás, Brazil (13°34'17"S, 48°06'58"W). In one specimen of *L. poecilogyrus* (Centro de Estudos e Pesquisas Biológicas - CEPB 4427, male SVL 546.2 mm) we found an adult female *Phrynohyas venulosa* (SLV 61.6 mm) and the other (CEPB 4496, female SVL 432.7 mm) had most of the posterior limbs and pelvic region of a specimen of *Hyla multifasciata* (Femur: 25.2 mm; Tibia: 29.1 mm; Tarsus: 17.2 mm).

Some authors have mentioned that *L. poecilogyrus* feeds on amphibians (Vanzolini et al. 1980. Répteis das Caatingas. Acad. Bras. de Ciencias Ed. Rio de Janeiro. 161 pp.; Marques et al. 2001. Serpentes da Mata Atlântica, Guia Ilustrado para a Serra do Mar, Holos Ed. Ribeirão Preto. 184 pp.), and some have mentioned species of the families Bufonidae (*Bufo granulosus, B. paracnemis*) and Leptodactylidae (*Leptodactylus fuscus, L. ocellatus, Physalaemus cuvieri*) (Norman and Naylor 1994. Amphibians and Reptiles of the Paraguayan Chaco, Vol. I. Private Publication. San José. 281 pp.), lizards (*Teius* sp.), fishes, birds, and small rodents (Cei 1993. Monogr. XIV, Mus. Reg. Sci. Nat. Torino. 949 pp.; Achaval and Olmos 1997. Anfíbios y Reptiles del Uruguai, Série Fauna n°1, Facultad de Ciencias Ed. Montevideo. 128 pp.). Young specimens may feed on insects and small amphibians and reptiles (Cei 1986. Monogr. IV, Mus. Reg. Sci. Nat. Torino. 527 pp.).

Our observations include two different species of hylid frogs in the diet of *L. poecilogyrus*. The most interesting observation is the

fact that both specimens preyed on two species of arboreal frogs, and *L. poecilogyrus* is considered to be a terrestrial species living near or in swamps.

Submitted by **NELSON JORGE DA SILVA JR., IVAN FRANÇA E SOUZA, WILIAN VAZ SILVA,** and **HÉLDER LÚCIO RODRIGUES SILVA**, Laboratório de Herpetologia, Centro de Estudos e Pesquisas Biológicas, Universidade Católica de Goiás, Ave. Universitária, 1440, Setor Universitário, 74.210-010, Goiânia, Goiás, Brazil (e-mail [NJS]: njs@ucg.br).

LYSTROPHIS NATTERERI (NCN). **PREDATION.** *Lystrophys nattereri* is a small terrestrial xenodontini that occurs from central to southern Brazil (Hoge et al. 1975. Mem. Inst. Butantan. 39:37–50). We are unaware of any reports of predators of *L. nattereri*. We present an instance of predation on *L. nattereri* by the white-tailed hawk, *Buteo albicaudatus* (Aves: Accipitridae). The observation occurred on 19 October 2000 at 0605 h on an unpaved road crossing an area of pristine flooded grassland (22°13'30"S, 47°54'00"W, 715 m elev.) in Itirapina Ecological Station (IES), municipality of Itirapina, São Paulo State, southeastern Brazil.

When first seen from a car, the hawk was on the ground pecking a snake held by its claws. The approaching car drove the hawk away from its prey, an adult female *L. nattereri* (404 mm SVL, 57 mm tail length, mass 43 g; with four enlarged follicles). While the still-living snake was examined by us, the hawk hovered over the area. The snake had a scar throughout the frontal scale.

Snakes are not a rare prey item for the white-tailed hawk in Brazil (M. A. Granzinolli, unpubl. data). This hawk hunts vertebrates by standing flight or hovering at 20–30 m above ground and diving over prey (M. A. Granzinolli, unpubl. data; pers. obs.). The color pattern of *Lystrophis nattereri* is similar to that of the syntopic pitviper, *Bothrops itapetiningae*, suggesting the former is a mimic of the latter; indeed, the geographic distributions of both species in Brazil are largely coincident (see Hoge et al., *op. cit.*; Campbell and Lamar 1989. The Venomous Reptiles of Latin America, Comstock, Ithaca, New York. 425 pp.).

The snake is deposited in the Museu de História Natural, Universidade Estadual de Campinas (ZUEC 02472). D. Zanchetta and the staff of Instituto Florestal allowed and facilitated our fieldwork at IES, and M. A. Grazinolli provided unpublished data and discussed with us hawk feeding habits. This is the publication number 4 of the project Ecology of the Cerrados of Itirapina, funded by FAPESP.

NERODIA ERYTHROGASTER FLAVIGASTER, N. RHOMBIFER,* and *N. SIPEDON PLEURALIS (Yellow-bellied, Diamond-backed, and Midland Watersnakes). **FORAGING BEHAVIOR.** The use of man-made items by animals is varied. The loggerhead shrike (*Lanius ludovicianus*) uses barbed wire in nest construction and prey capture (Burton 1999. Am. Midl. Nat. 142:198–199). Desert tortoises (*Gopherus agassizii*) construct their burrows near roads and the concrete bases of wind energy structures (Lovich and Ramona 2000. Chel. Conserv. Biol. 3:714–721). Here we report the novel use of a man-made structure in the foraging strategy of three sympatric species of water snakes.

We monitored the habitat use by individuals of *Nerodia erythrogaster flavigaster*, *N. rhombifer*, and *N. sipedon pleuralis* in Nashoba Park (Germantown, Shelby County, Tennessee, USA; 35°07'N, 89°48'W) using a mark-recapture technique during summer 1998 (18 June–18 September). The park contains an impoundment ca. 2 acres in area and bounded on the northern end by a concrete retaining wall ca. 50 m long. We noticed that precipitation events of a certain magnitude caused the impoundment to overflow the retaining wall, carrying fish (*Lepomis cyanellus* [green sunfish], *L. macrochirus* [bluegill], *Ameirus melas* [black bullhead catfish], *Gambusia affinis* [mosquitofish], and *Labidesthes sicculus* [brook silverside]) into a recess on the other side. We never observed snakes being washed over the wall, but did observe animals moving across the wall under their own power. On five occasions, we observed animals foraging in the ephemeral pools caused by overflow. We found a single *N. rhombifer* (R8: 42.8 cm SVL, 96 g mass) with a large food bolus indicative of successful prey capture on 11 August 1998 at 21:26 h. Two *N. sipedon pleuralis* (S6: 64.8 cm SVL, 196 g mass; S7: 56.8 cm SVL, 136 g mass) were captured in the pools on 13 July 1998 at 20:47 h and 21:42 h, respectively. A third *N. sipedon pleuralis* (S10: 78.5 cm SVL, 525 g mass) was captured on 30 July 1998 at 21:38 h. A single *N. erythrogaster flavigaster* was captured in the pools on two separate occasions (30 July 1998: 78.0 cm SVL, 375 g mass and 03 August 1998: 79.5 cm SVL, 350 g mass).

During casual monitoring in 1999, we observed two additional occurrences of foraging in the pools. On 21 May 1999, a *N. sipedon pleuralis* (25.8 cm SVL) was found, and a *N. rhombifer* (81.0 cm SVL) was found on 19 July 1999. We did not systematically survey the retaining wall area following every rain, but would expect animals to be found there at those times. We can report that no animals were found in the recessed area during any surveys at times when the pools were dry. We suggest that these observations represent a unique strategy in which the animals inhabiting this impoundment associate precipitation events with the availability of food items in a confined area and forage there to maximize prey capture.

OXYRHOPUS MELANOGENYS (Calico Snake). **DEFENSIVE BEHAVIOR.** The coiling of the tail and exuding an odiferous musk has been well documented as a defensive ploy used by many snake species (Fitch 1975. Univ. Kansas Mus. Nat. Hist. Misc. Publ. 62:1–53; Greene 1973. J. Herpetol. 7:143–156). Herein I report an incident involving a juvenile *O. melanogenys* using a

defensive tail display.

On 1 January 2000 at 2300 h a juvenile (26.5 cm SVL, 9 cm TL, 5 g mass) was found crossing a trail in secondary forest in the Madre Selva 2 Biological Reserve in Loreto, Peru. When touched, the snake placed its head beneath its body coils, raised the posterior portion of its body, coiled its tail into a raised spiral, and emitted a strong, odiferous musk. This specimen was measured, weighed, and released.

Submitted by **CARL J. FRANKLIN,** 1001 Denmark Drive, Grand Prairie, Texas 75050, USA; e-mail: HERPKING@ix.netcom.com.

OXYRHOPUS RHOMBIFER RHOMBIFER (Falsa-coral). **DIET**. Although dietary habits are largely unknown for most snake species of the tribe Pseudoboini, existing data suggest that snakes of this group feed primarily on small mammals and lizards (Duellman 1978. Misc. Publ., Univ. Kansas Mus. Nat. Hist. 65:1–352; Marques et al. 2001. Serpentes da Mata Atlântica: Guia Ilustrado para a Serra do Mar. Holos Editora, Ribeirão Preto, São Paulo. 186 pp.; Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150). *Oxyrhopus r. rhombifer* is a terrestrial, mainly nocturnal, pseudoboine snake that ranges from southeastern and southern Brazil to northeastern Argentina and Uruguay (Bailey 1970. U.S. Nat. Mus. Bull. 297:229–235). Data on the diet of this snake come from different geographical areas, resulting mainly from opportunistic observations, and are fragmentary. Known prey items are small lizards (Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Museo Rergionale di Scienze Naturali. 950 pp.; Yanosky et al. 1996. Herpetol. Nat. Hist. 4:97–109), rodents (Lema et al. 1983. Comun. Mus. Ci. PUCRS 26:41–121), and anurans (Yanosky et al., *op. cit.*).

We dissected one adult male *Oxyrhopus r. rhombifer* from the municipality of Santa Maria (29°43'S, 53°42'W), Rio Grande do Sul state, Brazil (Zoology Collection, Universidade Federal de Santa Maria [ZUFSM 1359]; SVL = 390 mm, fixed weight = 38.7 g), and found in its stomach a single glass snake (*Ophiodes* sp., ZUFSM 239 [prey items collection]; SVL = 200 mm, fixed weight = 22.5 g). The glass snake was swallowed head first. This is the first record of *Ophiodes* as a food item of *Oxyrhopus r. rhombifer*, as well as the first record of a relatively large and elongated lizard (SVL = 51% of the snake SVL) for the species.

We thank Robert A. Thomas for making useful comments on earlier versions of this manuscript. One of us (GFM) benefited from a graduate fellowship from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).

Ipiranga, 6681, CEP 90619-900, Porto Alegre, Rio Grande do Sul, Brazil, and **SONIA TEREZINHA ZANINI CECHIN**, Departamento de Biologia, Setor de Zoologia, Universidade Federal de Santa Maria, Faixa de Camobi, km 9, Santa Maria, Rio Grande do Sul, Brazil, CEP 97105-900 (e-mail: cechinsz@ccne.ufsm.br).

***PHILODRYAS PATAGONIENSIS*. DIET**. *Philodryas patagoniensis* is a terrestrial colubrid reaching a maximum total length of 150 cm (Cei 1993. Reptiles del Noroeste, Noreste y Este de Argentina. Herpetofauna de las Selvas Subtropicales, Puna y Pampas. Mus. Reg. Sc. Nat. Torino, Monogr. 14:575), and ranging over a large area of South America (Giraudo 2001. Serpientes de la Selva Paranaense y del Chaco Húmedo. L.O.L.A. Argentina., Monogr. 17:157). Reported prey consists of a variety of vertebrates including amphibians, lizards, snakes, birds, and mammals.

In this note, I report on prey items obtained from stomach dissection of 53 museum specimens (mean SVL = 705 mm; range = 213–1315 mm; N = 46) from Corrientes, Entre Ríos, Formosa, Misiones, Santiago del Estero, and Santa Fe provinces in central and northeastern Argentina and in Uruguay. Specimens were examined in the following collections: Instituto Nacional de Limnología, Consejo Nacional de Investigaciones Científicas y Técnicas, Santa Fe (INALI; 50 specimens), Félix de Azara collection, now deposited in the Museo Argentino de Ciencias Naturales, Buenos Aires (MACN; 2 specimens); Museo Provincial de Ciencias Naturales Florentino Ameghino, Santa Fe (MFA; 1 specimen). Museum numbers for material examined are available from the author upon request. Prey items were deposited in the Instituto Nacional de Limnología.

Twenty-six *P. patagoniensis* (49.05% of the specimens examined) contained recoverable food items. I found 29 prey items, of which 8 (27.58%) were lizards, 6 (20.68%) were amphibians, 6 (20.68%) were mammals, 4 (13.79%) were snakes, 4 (13.79%) were birds (possibly young birds), and 1 (3.4%) was an unidentified vertebrate (Table 1). These data confirm that *Philodryas patagoniensis* is a general predator, consuming a variety of terrestial vertebrates.

I thank Alejandro Giraudo for his unselfish help to conclude this work, assistance in the field, access to his personal library, and valuable suggestions on the manuscript. I thank Vaneza

TABLE 1. Prey eaten by *Philodryas patagoniensis* based on examination of stomach contents of preserved specimens.

Prey taxon	Prey frequency	% of total prey items
Amphibians		
Leptodactylus gracilis	2	6.89
Bufo granulosus aff. *fernandezae*	2	6.89
Unidentified amphibians	2	6.89
Reptiles		
Mabuya dorsivitatta	3	10.34
Mabuya sp.	1	3.44
Pantodactylus schreibersii	3	10.34
Unidentified lizard	1	3.44
Unidentified colubrid snake	3	10.34
Liophis dilepis	1	3.44
Birds	4	13.79
Mammals		
Holochilus brasiliensis	1	3.44
Unidentified mammals	5	17.24

PSEUSTES SULPHUREUS (Amazon Puffing Snake). **DIET.** Forest dwelling snakes are poorly studied because they are difficult to find and catch. Here we report an event of *Pseustes sulphureus* feeding on a little tinamous (*Cryptorellus soui;* Tinamidae) in the Ecuadorian rainforest.

A specimen of *P. sulphureus* was caught on 24 April 2000 at 0930 h at the Tiputini Biodiversity Station (Tiputini River, Amazon Basin), Ecuador. The snake was discovered basking in a tree 1.5 m above ground, in a patch of sunlight that penetrated to the understory. The individual measured 249.5 cm in total length, 211 cm in snout–vent length, and weighed 345 g. After 24 h of captivity in a cloth bag it defecated the remains of a bird that was identified as a *C. soui.* This bird is a fairly common ground-dwelling species with an average mass of 188 g.

Data for this contribution were collected during the activities, and as a byproduct, of a course of tropical ecology by Boston University and Universidad San Francisco de Quito at Tiputini Biodiversity Station. We thank M. Lentino for sharing unpublished information on *C. soui.* We also thank M. Rodriguez and S. Seger for help with fieldwork and identification of the sample.

Submitted by **JESÚS A. RIVAS,** 5105 Trenton Road, Knoxville, Tennessee 37920, USA, and **STEPHANIE KANE,** 6 Marblestone Lane, South Setauket, New York 11720, USA.

REGINA SEPTEMVITTATA (Queen Snake). **ABERRANT PATTERN.** The typical distinguishing pattern for this species of *Regina* within the genus includes four ventral rows of stripes or rarely spots. Tulane University Museum of Natural History TU 15362 from one mile east of Brown's Crossroads, Dale County, Alabama, USA has an immaculate venter. Use of a key such as that by Powell et al. (1998. A Key to Amphibians and Reptiles of the Continental United States and Canada. University Press of Kansas, Lawrence) would yield an identification of *Regina grahamii*, a species unrecorded from Alabama. However, scutellation of the odd *R. septemvittata* clearly separates the two species. *R. septemvittata* has been recorded from Dale County (Mount 1975. The Reptiles and Amphibians of Alabama, Auburn University Agricultural Experiment Station, Auburn, Alabama). Identity verified by Jeff J. Boundy.

Submitted by **HAROLD A. DUNDEE**, Tulane University Museum of Natural History, Belle Chasse, Louisiana 70037-3098, USA; e-mail: dundee@museum.tulane.edu.

RHADINAEA MONTANA (Nuevo Leon Graceful Brown Snake). **HABITAT AND DIET**. Little is known about the ecology or natural history of *Rhadinaea montana*. This species has only been documented in Nuevo León, México, from near Ojo de Agua near Galeana (type locality), La Huasteca, Monterrey (Myers 1974. Bull. Amer. Mus. Nat. Hist. 153:89–91), Ojo de Agua in Pablillo (Chaney and Liner 1986. Herpetol. Rev. 17:67), and near Las Adjuntas (Chaney and Liner 1990. Herpetol. Rev. 21:23). Liner and Chaney (1987. Herpetol. Rev. 18:37) found a specimen near a spring in a riparian area in pine-oak habitat and provided the first habitat description for this species. No specific dietary records exist for *R. montana*. Sazima et al. (1992. Herpetol. Rev. 23:120–121) reported on the diet of *R. bilineata*, and stated that the small size, elongated head, and slender body of this species appeared well-suited to predating on small frogs. Herein we provide an additional habitat description for *R. montana* and report the first recorded prey item for this rare species.

On 31 May 2001 we collected an adult male *R. montana* (308 mm SVL) from under a dead lechugilla (*Agave lechugilla*) in a canyon bottom west of San Isidro, Municipio Santiago, Nuevo León, México. The canyon (ca. 1600 m elevation) is characterized by steep limestone walls covered with various agaves (*Agave* spp.), sotol (*Dasylirion* sp.), and scrub oak (*Quercus* sp.), and has intermittent pools of water. The specimen was found ca. 1 m away from a juvenile *Crotalus lepidus*.

Upon inspection of the *R. montana*, a noticeable mid-body bulge was evident. Dissection of the stomach in the lab revealed the bulge to be a partially digested adult *Syrrhophus longipes* that had been swallowed feet first. Our findings on *R. montana* are in agreement with Sazima et al. (*op cit.*). The specimen and prey item were deposited in the Universidad Autónoma de Nuevo León herpetological collection (UANL 5842).

We thank James R. Dixon for his assistance.

Submitted by **ROBERT W. BRYSON, JR.**, Department of Biology, Sul Ross State University, Alpine, Texas 79832, USA, **JAVIER BANDA**, and **DAVID LAZCANO**, Laboratorio de Herpetología, Universidad Autónoma de Nuevo León, Apartado Postal - 513, San Nicolas de los Garza, Nuevo León, C.P. 66450, México.

SENTICOLIS TRIASPIS (Green Ratsnake). **REPRODUCTION.** *Senticolis triaspis* occurs from southeastern Arizona,USA, and southern Tamaulipas, Mexico southward along slopes of the Mexican highlands to Costa Rica (Stebbins. 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin, Boston. 336 pp.). There is reproductive information on female *S. triaspis* from the Yucatan, Mexico in Censky and McCoy (1988. Biotropica 20:326–333) including a mean clutch size of 4.8 ± 1.4 SD, range 3–7 for 11 females and in Dowling (1960. Zoologica 45:53–80) who reported a clutch of two oviductal eggs from October. Rossi and Rossi (1995. Snakes of the United States and Canada: Keeping them Healthy in Captivity. Volume 2 Western Area. Krieger Publishing Company, Malabar, Florida. 325 pp.) reported a female captured on 25 April laid four eggs on 4 July. The purpose of this note is to report on an examination of *S. triaspis* gonads from the herpetology collections of the Natural History Museum of Los Angeles County, Los Angeles (LACM), and The University of Arizona, Tucson (UAZ) and to provide the first information on the testicular cycle.

Fifteen *S. triaspis*, 7 males, mean snout–vent length, SVL = 674 mm ± 95 SD, range = 536–813 mm; 8 females, mean SVL = 852

mm ± 166 SD, range = 675–1063 mm were examined. Snakes were collected 1953–1981. The left gonad was removed, dehydrated in alcohol and embedded in paraffin. Histological sections were cut at 5 μm and stained in Harris' hematoxylin from all snakes except UAZ 27041 which contained enlarged ovarian follicles and LACM 6833 which contained oviductal eggs.

Three of eight (38%) females examined were reproductively active. One July female (LACM 127781; 717 mm SVL) from Sonora, Mexico was in early yolk deposition as evidenced by a ring of yolk granules inside one follicle. One September female (UAZ 27041; 704 mm SVL) from Jalisco, Mexico contained 5 enlarging ovarian follicles, 15–19 mm length. One October female (LACM 6833; 873 mm SVL) from Sinaloa, Mexico, contained 5 oviductal eggs. Other females (LACM 6824, 64447; UAZ 41363, 47028) had inactive ovaries: June (1), July (2), August (1). Ovarian follicles from one October female from Santa Cruz County, Arizona, USA (UAZ 46548, 1005 mm SVL) were undergoing atresia (degeneration).

Five of the seven (71%) male *S. triaspis* were undergoing spermiogenesis: June (LACM 136919, 536 mm SVL) Nayarit, Mexico; July (LACM 6823, 626 mm SVL) Sinaloa, Mexico; September (UAZ 34522, 780 mm SVL) Cochise County, Arizona, USA; November (2) (UAZ 32544, 660 mm SVL) Sonora, Mexico, (UAZ 33293, 670 mm SVL) Santa Cruz County, Arizona, USA. A testis from one December male (UAZ 24913, 813 mm SVL), from Nayarit, Mexico was in late spermiogenesis. The germinal epithelium was exhausted and contained only a few layers of cells. There were small clusters of sperm lining portions of the lumina of the seminiferous tubules. A testis from one June male (UAZ 24916, 632 mm SVL) from Cochise County was in recrudescence (recovery). Numbers of germ cells had increased and primary spermatocytes were the predominant cell.

The above observations on females (yolk deposition in July, enlarged follicles in September and oviductal eggs in November) and males (spermiogenesis from June to September) support the statement of Censky and McCoy (*op. cit.*) that reproduction in *S. triaspis* appears to be aseasonal or continuous.

I thank David A. Kizirian (Natural History Museum of Los Angeles County) and Charles H. Lowe (University of Arizona) for permission to examine *S. triaspis*.

Submitted by **STEPHEN R. GOLDBERG**, Department of Biology, Whittier College, Whittier, California 90608, USA.

SIBYNOMORPHUS VENTRIMACULATUS (Southern Snail-eater). **MATING**. Data concerning the reproductive biology of this South American dipsadine are scarce and copulation in nature is unreported. On 3 February 2000 at 0730 h, one of us (SC) observed a pair of *S. ventrimaculatus* copulating in Pinhal Grande, southern Brazil (29°20'46"S, 53°18'24"W). The tails of the male (SVL 382 mm, TL 105 mm, 24 g) and female (SVL 415 mm, TL 82 mm, 28 g) were intertwined and the right hemipenis of male was inserted into the female's cloaca. The snakes were positioned 1 m above ground on a *Bauhinia forficata* bush (Fabaceae).

Upon dissection of the female, the largest follicle measured 6.7 mm (maximum diameter), suggesting a non-vitellogenic period (Oliveira 2001. Ecologia de Três Espécies de Dormideira, *Sibynomorphus* (Serpentes: Colubridae). MS. Dissertation. Univ. São Paulo, São Paulo, SP. 60 pp.). Females of *Sibynomorphus ventrimaculatus* display a seasonal reproductive cycle. Secondary vitellogenesis occurs mainly from October to December and females lay eggs mostly in November and early December (Oliveira, *op. cit.*). The present observation suggests that there is a delay between mating and fertilization..

The snakes were deposited in the collection of Departamento de Biologia, Zoologia of Universidade Federal de Santa Maria (ZUFSM 1898 female; ZUFSM 1899 male). We thank Ana Beatriz Barros de Morais, Alessandro M. Mazzoni, Felipe Spina, Otávio A. V. Marques, and Selma de Almeida Santos for helpful comments.

Faixa de Camobi, KM 9, Camobi, CEP: 97105-900, Santa Maria, RS, Brazil (e-mail: cechinsz@ccne.ufsm.br), and **JULIANA LIMA OLIVEIRA**, Departamento de Ecologia, Instituto de Biociências, Universidade de São Paulo, R. do Matão, Trav. 14, 321, CEP 05508-900, São Paulo, SP, Brazil (e-mail: jlima@ib.usp.br).

SONORA AEMULA (File-tailed Ground Snake). **REPRODUCTION.** *Sonora aemula* is known from Sonora, Chihuahua, and Sinaloa, Mexico (Flores Villela and Gerez 1994. Biodiversidad y Conservación en México: Vertebrados, Vegetación y uso del Suelo. Comision Nacional para el Conocimiento y uso de la Biodiversidad y Universidad Nacional Autónoma de México, Ciudad Universitaria, D.F. México. 439 pp.). There are no reports on reproduction in this species. The purpose of this note is to report on an examination of gonadal material from 10 *S. aemula* (5 males, mean snout–vent length, SVL = 260 mm ± 28 SD, range 233–307 mm, 5 females, SVL = 257 mm ± 40 SD, range 203–309 mm) from Sonora, México. Snakes were borrowed from Arizona State University (ASU) and the University of Arizona (UAZ). Gonads were dehydrated in ethanol and embedded in paraffin. Histological sections were cut at 5 μm and stained with Harris' hematoxylin followed by eosin counterstain. Enlarged ovarian follicles (> 8 mm length) were counted, no histology was done on them.

Testes of four males from July were undergoing spermiogenesis (sperm formation) (ASU 5850, SVL 307 mm; ASU 5851, SVL 250 mm; ASU 6458, SVL 253 mm; UAZ 46685, SVL 256 mm. One male from November (UAZ 45149, SVL 233) was in the early stages of testicular recrudescence (renewal of germinal epithelium for the next period of spermiogenesis).

One female from July (ASU 6611, SVL 280 mm) contained four enlarged ovarian follicles (> 8 mm length); one July female (ASU 6612, SVL 203 mm) was not undergoing yolk deposition and may have been immature. One female from August (UAZ 45155, SVL 251 mm) contained four enlarged follicles (> 11 mm length). Ovaries from one female from August (UAZ 45157, SVL 309 mm) and one from November (UAZ 45152, SVL 243 mm) were not undergoing yolk deposition.

The finding of two *S. aemula* with clutch sizes of four each are within the range (3–6) reported for the congener *S. semiannulata* from Arizona (Goldberg 2001. Southwest. Nat. 46:387–391). Goldberg *(op. cit.)* reported spermiogenesis in 2/3 July *S. semiannulata* males from Arizona.

I thank G. Bradley (UAZ) and A. Holycross (ASU) for permission to examine specimens.

Submitted by **STEPHEN R. GOLDBERG,** Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

THAMNOPHIS CYRTOPSIS COLLARIS (Black-Necked Garter Snake). **DIET**. The diet of *Thamnophis cyrtopsis* is well documented within some portions of its range (Fouquette 1954. Texas J. Sci. 6:172–188; Jones 1990. Southwest. Nat. 35:115–122); however, no diet records exist for this snake from southern and central Mexico. The diet of *T. cyrtopsis* consists of anurans (tadpoles and adults), skinks, and fishes (Wright and Wright 1957. Handbook of Snakes of the United States and Canada, 2 vols. Comstock Publ., Ithaca, New York. 1105 pp.). On 28 October 2000 at 0955 h in a semiarid area called "El Charcote," 6 km SW of Zapotitlán Salinas (18°20'N, 97°26'W), Puebla, Mexico, at an elevation of ca. 1600 m, we observed an adult female *T. c. collaris* (799 mm SVL; KAB043) capturing an adult male *Bufo occidentalis* (77 mm SVL; KAB044) near a flowing spring. The snake had taken the toad's forefoot and a portion of the toad's flank into its mouth. The toad struggled and was able to escape when we attempted to photograph the incident. The toad retreated into a puddle and remained motionless for ca. 7 min. This is the first report of *T. c. collaris* preying on *B. occidentalis* from this region of Mexico.

Submitted by **KARLA ABBADIÉ-BISOGNO, LUIS OLIVER-LÓPEZ,** and **AURELIO RAMÍREZ-BAUTISTA,** Laboratorio de Ecología, Unidad de Biología, Tecnología y Prototipos (UBIPRO), Escuela National de Estudios Profesionales-Iztacala, UNAM. Av. De Los Barrios s/n, Los Reyes Iztacala, Tlalnepantla, Edo. de México, C.P. 54090, A.P. 314.

THAMNOPHIS HAMMONDII (Two-striped Garter Snake). **PREY**. *Thamnophis hammondii* is considered one of the most aquatic of the garter snakes and is closely associated with streams, creeks, and pools (Fitch 1940. Univ. California Publ. Zool. 44:1–150). Reported diet of *T. hammondii* includes mostly aquatic prey such as tadpoles, frogs, toads, fish, fish eggs, and to a lesser extent terrestrial species such as earthworms (Jennings and Hayes 1994. Amphibian and Reptile Species of Special Concern in California. CA Dept. Fish Game. Final report contract no. 8023, 255 pp.; Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. University of Oklahoma Press, Norman. 332 pp.). Herein we provide the first report of a terrestrial salamander and an aquatic leech as prey items for *T. hammondii*. In all cases, prey was determined by the examination of stomach contents. Upon capture, each snake was hand palpated until the stomach contents were disgorged.

At 1145 h on 11 May 2001, ELE and MLW captured an adult *T. hammondii* (350 mm SVL, wt. not available) on the shore of a cement-lined reservoir (diameter = 35 m) on the Rancho Jamul Ecological Reserve, San Diego County, California,USA (32°41'11"N, 116°51'14"W; 269 m elevation). The surrounding vegetation community is a mosaic of coastal sage scrub (*Eriogonum fasciculatum, Artemisia californica, Isocoma menziesii*) and non-native grassland (*Avena barbata, Bromus* spp., *Brassica nigra, Erodium botrys*). Upon processing, the material regurgitated from the snake consisted entirely of a terrestrial salamander species, *Batrachoseps major*. In total, two bodies minus tails (27 mm and 36 mm snout–vent length [SVL]), six tail tips (7 mm, 14 mm, 26 mm, 36 mm, 39 mm, 42 mm), and one tail segment (10 mm), were recovered. Limited digestion of the epidermis on only one small tail tip and the single tail segment suggests that these food items had most likely been consumed within a few hours prior to capture (H. Greene, pers. comm.). The *B. major* tissue was deposited in the herpetology department of the California Academy of Science (CAS 223811).

To extend the escape time or prevent capture, *Batrachoseps* have the ability to autotomize their tail in response to a threat. The wriggling motion of the detached tail increases the salamander's chances of survival by distracting the predator's attention (Brodie 1977. Copeia 1977:523–535). The ratio of tail tips to bodies (6:2) suggests that several *B. major* successfully escaped using this strategy, albeit tailless. Additional antipredatory mechanisms exhibited by *Batrachoseps* include looping the tail around a snake's head and neck and immobilizing the snake with adhesive skin secretions. This response to attack proved effective in encounter trials with juvenile garter snakes (Arnold 1982. Copeia 1982:247–253). However, for the snake we captured, it is likely that the relatively small size of the salamanders, in relation to the gape (gape index = 86.8; following Miller and Mushinsky 1990. Copeia 1990:1099–1106) of the adult *T. hammondii,* enabled the snake to successfully consume the salamanders.

The stomach contents of a second adult *T. hammondii* (485 mm SVL, mass not available) captured at 1150 h consisted of one moderately digested *Rana catesbeiana* larva (TL = ~ 70 mm).

On 5 June 2001, ELE and SJM captured twelve *T. hammondii* at Lake-of-the-Woods in the Cleveland National Forest, San Diego County, California, USA [32°52'30"N, 116°27'58"W, 1635 m elevation]. The size of the snakes ranged from 332–480 mm SVL, 17–54 g in mass, and the male:female ratio was 3:1. When the stomach contents were examined, six of the twelve snakes contained identifiable material. The only items recovered from the six snakes were leeches, *Erpobdella* sp. (Hirudinea: Erpobdellidae). The quantity of leeches recovered from the six snakes was 1, 2, 2, 3, 6, and 6, respectively. Of the 20 leeches recovered, 14 were still alive, while 6 were dead and partially digested. As a result of improper preserving techniques of the leech specimens on site, the vouchers could only be positively identified to genus. The series of leeches have been deposited in the invertebrate collection of the University of Colorado Museum, Boulder. (UCM Invertebrates 2409).

We sampled the dense submergent vegetation (i.e., *Myriophyllum* sp., *Potamogeton nodosus*) from which the snakes were captured with ten 1-m sweeps, with a 30.5 cm D-net, to determine what aquatic organisms co-occurred with the leeches. Organisms captured by the net included: Annelida (Hirudinea), Amphipoda (Talitridae), Odonata nymphs (Anisoptera [2 var.], Zygoptera), Hemiptera (Gerridae, Notonectidae, Belostomatidae, Corixidae), Coleoptera larvae (Hydrophilidae), Gastropoda (*Planorbidae, Physidae*), and tadpoles (*Hyla regilla*). It is worth noting that of all the organisms captured by net, only leeches were detected in any of the stomachs of the 12 snakes examined on this date.

On 28 May 2002, SJM and ELE captured an additional 10 *T.*

hammondii at Lake-of-the-Woods. The size of the snakes ranged from 303–431 mm SVL, 12–38 g in mass, and the male:female ratio was 1:1. Two of the *T. hammondii* had leeches only in their stomach contents (the other 8 snakes' stomachs were empty). The quantity of leeches recovered from each of the two snakes was 1 and 3, and all leeches were dead. This information indicates a consistent use of this prey type between years.

Our thanks to Terri Stewart and Tim Hovey of California Department of Fish and Game for providing access to the Rancho Jamul Ecological Reserve and logistical support, Shi-Kuei Wu of University of Colorado Museum for identifying the leeches, and Andrew Bohonak of San Diego State University, Department of Biology, for assisting with arthropod identification. Norman Scott, Kathie Meyer, Rob Lovich, and John LaBonte provided useful comments on the manuscript. Permission to handle specimens was granted under California Department of Fish and Game permits issued to ELE and RNF. Fieldwork was funded in part by USGS, Western Ecological Research Center and Eastern Illinois University (SJM).

Submitted by **EDWARD L. ERVIN**[1], [1]U. S. Geological Survey, Western Ecological Research Center, 5745 Kearny Villa Road, Suite M, San Diego, California 92123, USA (e-mail: eervin@usgs.gov), **STEPHEN J. MULLIN**, Department of Biological Sciences, Eastern Illinois University, 600 Lincoln Avenue, Charleston, Illinois 61920-3099, USA (e-mail: cfsjm@eiu.edu), **MANNA L. WARBURTON**[1] and **ROBERT N. FISHER**[1].

THAMNOPHIS SCALARIS (Mexican Alpine Blotched Garter Snake). **DIET**. *Thamnophis scalaris* is an endemic Mexican species, occurring in high-elevation mountains of central Mexico (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman. 332 pp.). Although some information is available on the diet of *T. scalaris*, data from southern populations are lacking.

On 8 July 2000, a female *T. scalaris* (416 mm SVL, 2.9 g) was collected around a high elevation (2520 m) permanent pond located in San Cayetano, Estado de México, México (19°22'15"N, 100°05'22"W). This snake was deposited in Colección Nacional de Anfibios y Reptiles from the Universidad Nacional Autónoma de México (IBH-13762). The snake was forced to regurgitate a partially digested specimen of *Rana neovolcanica* (IBH-RF 017A–B; photographic vouchers). Previously documented prey are lizards, earthworms, and deer mice (Fouquette and Rossman 1963. Herpetologica 19:185–201; Lemos-Espinal and Ballinger 1992. Herpetol. Rev. 23:117; Venegas-Barrera and Manjarrez 2001. Herpetol. Rev. 32:266). This report is the first for an amphibian.

We thank Fausto R. Méndez for suggestions on the manuscript and for confirming identification of the snake and frog.

Submitted by **FELIPE RODRÍGUEZ ROMERO, GUSTAVO CASAS ANDREU**, and **LORENA LOPEZ GONZALEZ**, Departamento de Zoología, Instituto de Biología, Universidad Nacional Autónoma de México, A. P. 70-153, C. P. 04510. México D.F., México; e-mail (FRR): feliper@ibiologia.unam.mx.

THAMNOPHIS SIRTALIS SIRTALIS (Eastern Garter Snake). **PARTURITION**. A female eastern garter snake, *Thamnophis sirtalis sirtalis* (SVL 69.9 cm, incomplete tail 21.9 cm, mass 85.7 g), was collected at 1000 h on 21 July 2001 at the Mason Neck National Wildlife Refuge, Fairfax County, Virginia, USA. When captured, the female's cloaca was prolapsed, at the time considered a prelude to the release of musk. It was measured, weighed, and placed in a sealed bucket for transport to the laboratory for pit-tagging. When the bucket was opened at the laboratory an hour later, it was found that she had given birth to 16 young. A second group of 5 neonates was found at 1300 h, and a third group of 8 young were discovered at 1600 h. Twenty-eight neonates were alive when found, and one dead. Of the 28 live young, 27 were active (two made open-mouth threat displays), but one was limp and seemed weak. The next morning, two additional dead, desiccated neonates were found, but not measured or weighed, bringing the total litter size to 31. All neonates had a 2–3 scale-long umbilical scar on ventral scutes 17–19.

Standard measurements and weights were recorded from the first 29 neonates: total body length (TBL), mean 23.9 CM (21.0–25.1); snout–vent length (SVL), mean 15.7 cm (12.7–17.8); tail length (TL), mean 8.2 cm (7.6–9.7), TL/TBL, mean 34.2% (30.5–39.5); TL/SVL, mean 52.2% (43.9–65.3), and mass, mean 1.65 g (1.2–1.9). Regression of hatchling mass versus SVL was $y = 0.8579x + 14.282$ (R^2 0.026). SVL, mass, and TL/TBL fall within the ranges given for *T. s. sirtalis* by Rossman et al. (1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman, Oklahoma. 332 pp.), as does the litter size of 31, although this is a new record for northern Virginia (Ernst et al., 1997. Bull. Maryland Herpetol. Soc. 33:1–62). Total litter mass was 48 g, and the relative clutch mass (RCM) for the first 29 neonates was 0.56. Seigel and Fitch (1984. Oecologia 61:293–301) reported a range of RCMs for *T. sirtalis* of 0.244–0.426. The sex ratio of the 29 neonates was male biased 17:12.

Few data are available on the duration of parturition in *T. sirtalis*. Wood (1945. Copeia 1945:118) reported the birth of 57 young in 90 min (mean 1.57), Boyer (1941. Amer. Midl. Nat. 26:334–336) 27 young in 184.5 min (mean 6.83), and Wright (1988. Catesbeiana 8:31–32) 21 young in only 9 min (mean 0.43). The first 29 neonates in the present litter were born in 6 hours, in three groups of 16 (60 min, mean 3.75), 5 (120 min, mean 24.0), and 8 (180 min, mean 22.4), giving an overall mean duration between births of 2.48 min.

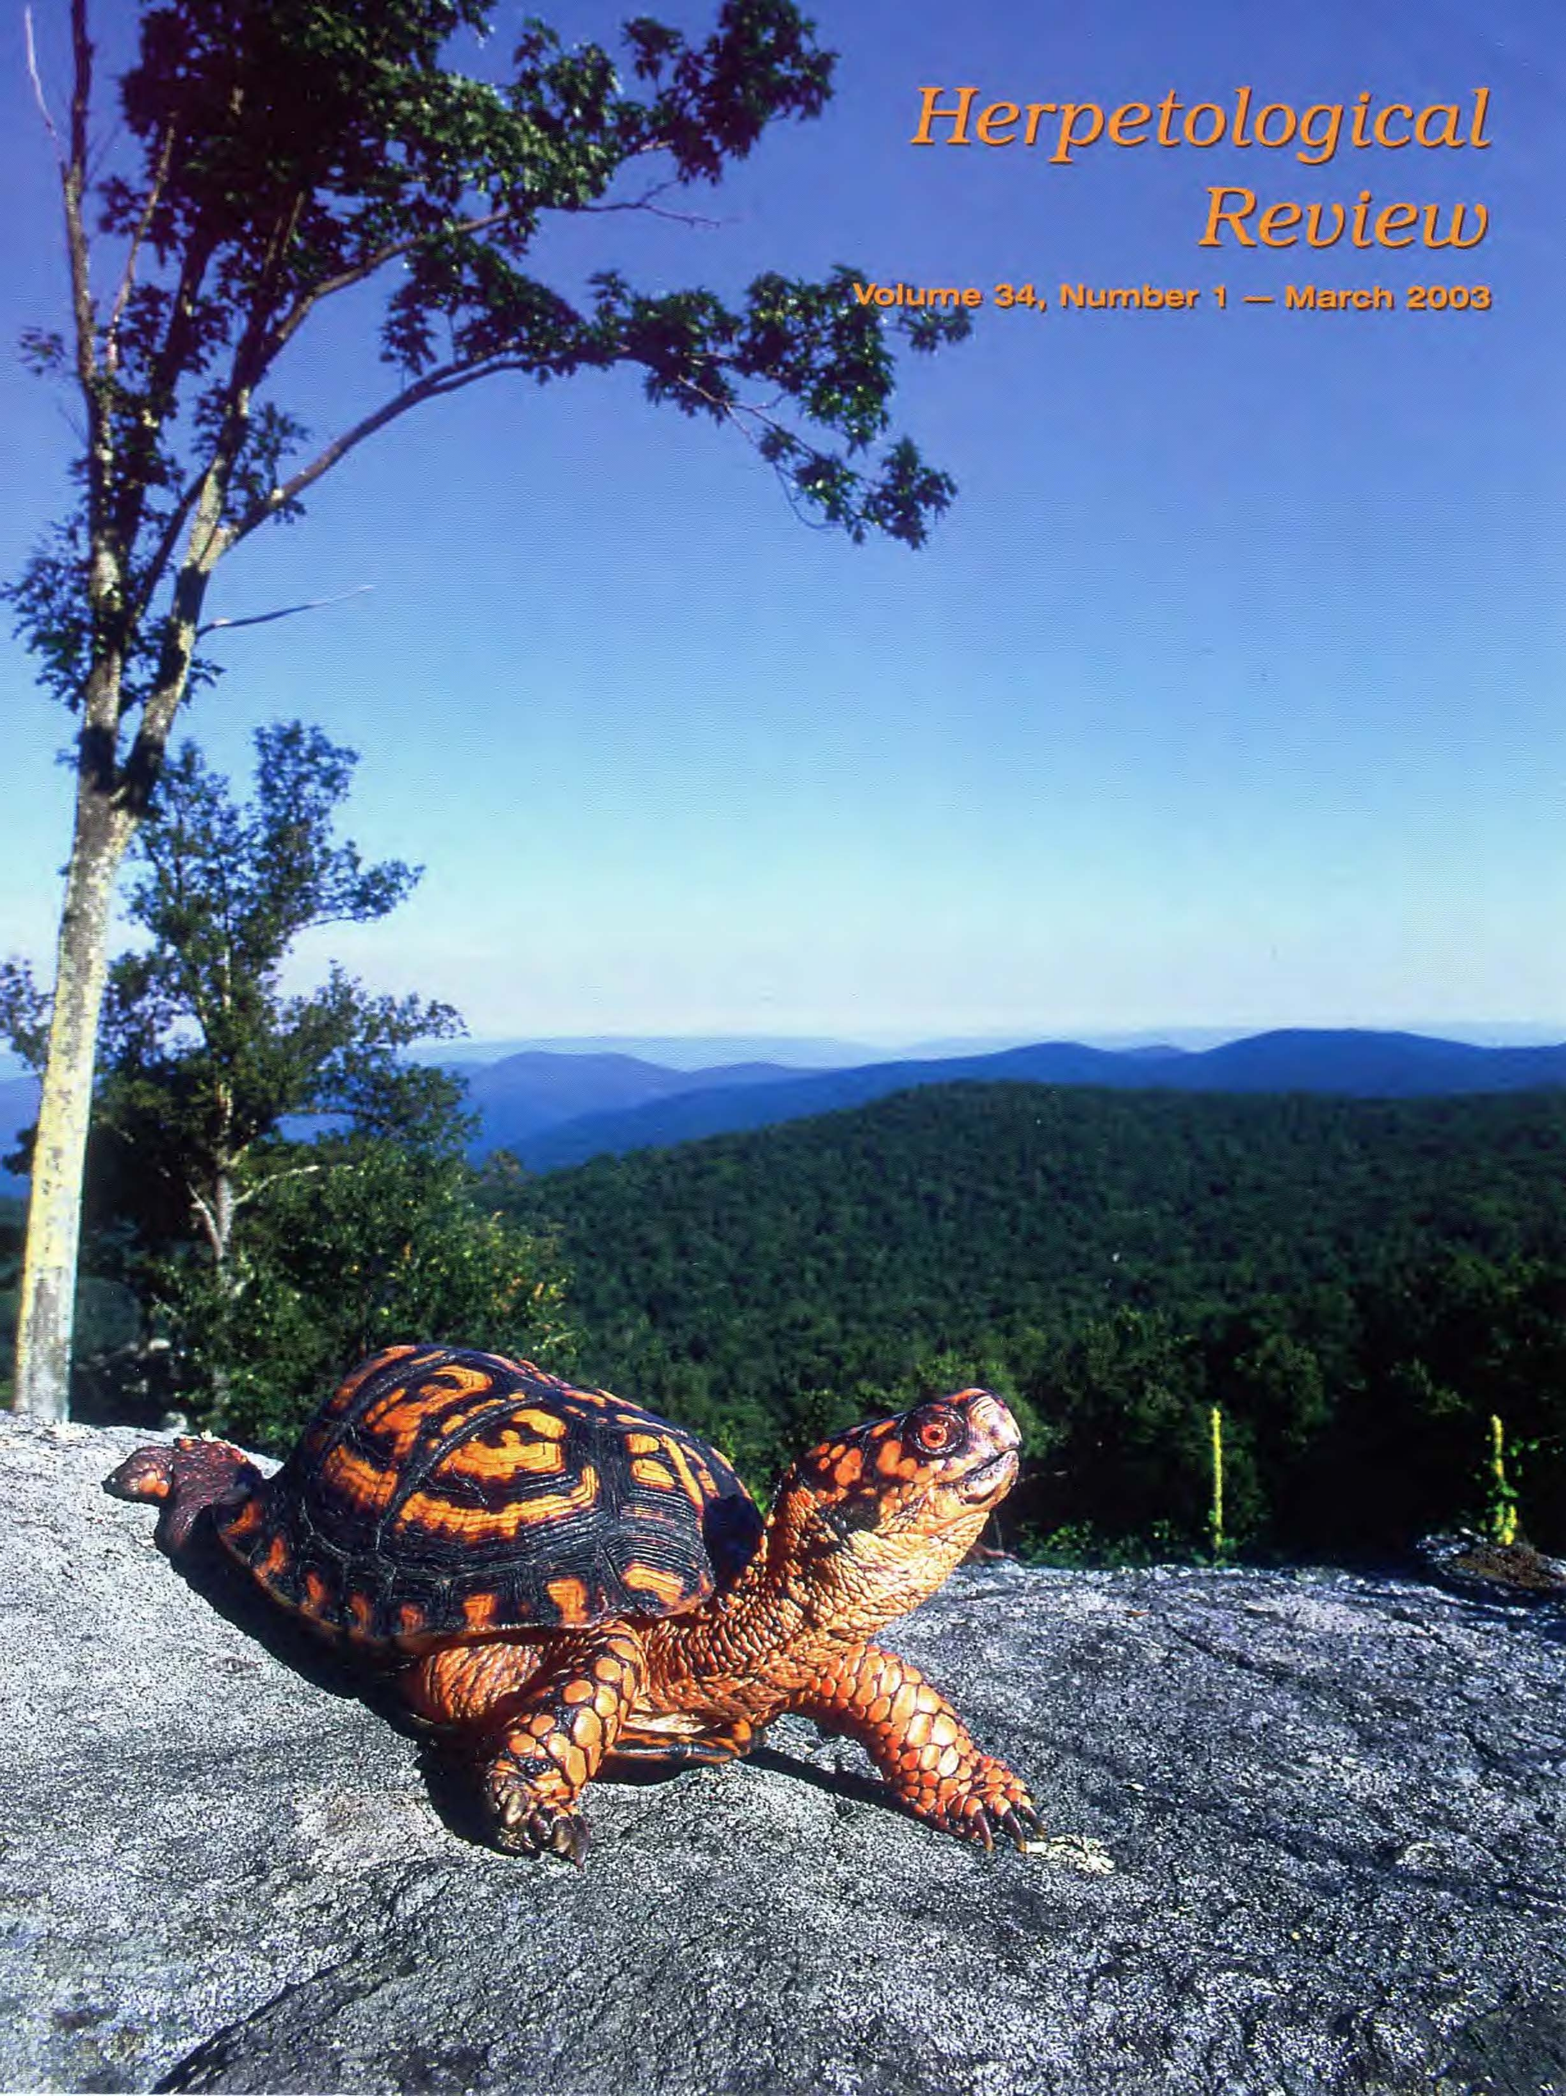
Herpetological Review

Volume 34, Number 1 — March 2003



HERPETOLOGICAL REVIEW

The Quarterly News-Journal of the Society for the Study of Amphibians and Reptiles

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ukans.edu/~ssar

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

ANNUAL DUES AND SUBSCRIPTIONS: Annual membership dues for the year 2003 in the Society for the Study of Amphibians and Reptiles are as follows: **REGULAR** membership US$60 (Student $30)—includes *Journal of Herpetology* and *Herpetological Review*; **PLENARY** membership US$80 (Student $45)—includes *JH*, *HR*, and annual subscription to the *Catalogue of American Amphibians and Reptiles*; **INSTITUTIONAL SUBSCRIPTION** $115—includes JH and HR. Additional fee for airmail postage outside USA $35 for one year. Additional membership categories available on the SSAR webpage: http://www.ukans.edu/~ssar/membership.html.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

Payment must be made in USA funds, payable to "SSAR," or by International Money Order, or with VISA or MasterCard (account number and expiration date must be provided). Payment should be sent to: Theodora Pinou, SSAR Treasurer, Peabody Museum of Natural History, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Fax: (203) 432-5176; e-mail: theodora.pinou@yale.edu

Future Annual Meetings

2003 — Hotel Tropical, Manaus, Brazil, 26 June–1 July (with ASIH, HL)
2004 — University of Oklahoma, Norman, Oklahoma (with ASIH, HL)
2005 — University of South Florida, Tampa, Florida (with ASIH, HL)

Society for the Study of Amphibians and Reptiles 2003 Annual Meeting

together with

The Herpetologists' League

and

American Society of Ichthyologists and Herpetologists

26 June – 1 July 2003
Tropical Hotel Conference Center
(on the Rio Negro)
Manaus, Amazonas, Brazil

Richard C. Vogt and Ning Labbish Chao, Local Chairs

Keynote Address: "In Search of El Dorado: The Neotropical Herpetofauna," by William E. Duellman (University of Kansas), The Herpetologists' League Distinguished Herpetologist for 2003.

SSAR President's Travelogue: "From the Amazonian Floating Meadows to the Surumoni Canopy Crane Project: Frog Research in Amazonia," by Walter Hödl (University of Vienna).

Symposium: "Reproductive Biology and Phylogeny of Urodela (Amphibia)." *Organizer:* David M. Sever, Saint Mary's College (dsever@jade.saintmarys.edu).

Symposium: "New Frontiers in Freshwater Turtle Ecology." *Organizers:* Richard C. Vogt, Instituto Nacional de Pesquisas da Amazônia–INPA (vogt@inpa.gov.br) and Paulo Andrade, IBAMA.

Symposium: "Amazonian Frogs: Taxonomic and Ecological Diversity." Organizers: Janalee P. Caldwell, University of Oklahoma (caldwell@ou.edu); William E. Duellman, University of Kansas; Albertina Lima, INPA.

Symposium: "Sequestered Defensive Compounds in Amphibians and Reptiles." *Organizer*: Alan H. Savitzky, Old Dominion University (asavitzk@odu.edu).

Symposium: "Disease Ecology and Global Amphibian Decline." *Organizers*: Mathew J. Parris, Memphis State University (mparris@memphis.edu); Andrew Storfer, Washington State University.

Symposium: "Amphibian Metamorphosis: 30 Years of Progress." *Organizer*: Christopher K. Beachy, Clarke College (cbeachy@keller.clarke.edu).

Symposium: "Exotics and Extinction: Fates of Fishes, Amphibians, and Reptiles in the Americas." *Organizers*: Harry Grier, University of Florida (harry.grier@fwc.state.fl.us) and Maria del Carmen Uribe Aranzabal.

Symposium: "The Biology of Hypogean Fishes, Amphibians, and Reptiles." Organizer: Aldemaro Romero, Macalester College (romero@macalester.edu).

Symposium: "Amazonian Herpetofauna." *Organizers*: Ermelinda Oliveira, Universidade Federal do Amazonas (ermeoliveira@uol.com.br); Richard C. Vogt, INPA.

SSAR Student Travel Awards: Awards of US $400 each are available. An applicant must be a student and a member of SSAR. Refer to page 243 of the December 2002 issue of *HR* for details.

Student Paper Awards: Henri Seibert prizes (US $200 each) will be awarded in five categories: Systematics, Ecology, Evolution, Conservation, and Physiology/Morphology. Refer to the official Meeting Announcement for details and to *HR* 28(4):175 for recommendations to students entering the Seibert competition.

Social Activities: General Reception, Graduate Student Reception, Picnic, Joint Meeting Banquet, SSAR/HL Silent Auction.

Field Trips: Several post-meeting field trips into the Amazon are planned. Refer to the meeting website for details.

Live Animal Exhibit: A large sample of reptiles and amphibians native to the Amazon region on display and available to photographers.

Costs: Preregistration (until 28 February) US $240 regular, $80 student, $110 accompanying person. From1 March–25 June 2003, costs are $290, $130 student. After 25 June, $340 regular, $180 student. Registration information available at: <http://www.aiha.org.br/reginfo.html>

Further Details: Refer to the official Joint Meeting website (www.aiha.org.br) for additional details, including travel requirements to Brazil.

About Our Cover: *Terrapene carolina*

The box turtles, consisting of four species in the genus *Terrapene*, have recently been reviewed in considerable detail by Dodd (2001. North American Box Turtles: A Natural History. Oklahoma University Press, Norman. 231 pp.). The Eastern Box Turtle (*Terrapene carolina*) group is made up of six extant subspecies ranging across much of the eastern United States and south to the Yucatán Peninsula of Mexico (Ernst and McBreen 1991. Cat. Am. Amphib. Rept. 512:1–13; Iverson 1992. A Revised Checklist with Distribution Maps of the Turtles of the World. Privately published. Richmond, Indiana. 363 pp.).

Much of what is currently known about the natural history and population biology of this wide-ranging species comes from a handful of long-term studies. Perhaps the best known of these studies is an ongoing project initiated in 1944 by Lucille Stickel at the Patuxent Research Refuge in Laurel, Maryland (Stickel 1978. Copeia 1978:221–225). The study site consists of an 11.8 hectare forested, floodplain along the Patuxent River. Beginning in 1945 and every ten years thereafter, this site's Eastern Box Turtle (*T. c. carolina*) population is surveyed. In the first 30 yrs of the study Stickel captured and marked 557 individual turtles. Despite the site's relative protection on the center's grounds, there is convincing evidence that a dam created upstream from the study site has contributed to a major decline of this population. The data that she and others (Hall et al. 1999. Biol. Cons. 88:165–172) have collected across five decades demonstrates the vulnerability of this species to human activities.

The turtle on the cover was photographed by **Will Brown** in Virginia's Shenandoah National Park during a 2001 herpetological inventory. Using only natural light, Brown used a 20mm Nikon lens on a Nikon N70 body, recording the image on Fuji Provia slide film. In addition to his work as a photographer, Brown is currently conducting herpetological research on several National Park Service properties. He began what he hopes to be another long-term box turtle study earlier this year. Through the use of radio-telemetry, Brown is studying the ecology of *T. c. carolina* residing at high elevations (760 to > 915 m) within the Blue Ridge Mountains of Shenandoah National Park. He is interested in corresponding with others studying the ecology of box turtles at higher elevations and can be reached at <wbrown@blueridgebiological.com>.

Brown took the photograph below at the Patuxent Research Refuge. This turtle, #3,8.10-11, was determined to be more than 20 yrs old when originally captured and marked by Lucille Stickel on 25 July 1949. Brown found this turtle again on 28 August 1999, making her at least 70 yrs old at that time. Appearing quite healthy, she could very well show up in the 2005 survey.

SSAR BUSINESS

SSAR Election Results

Results of the recent SSAR election are as follows:

President-Elect .... Robin Andrews.
Board of Directors (Class of 2005) ....
.... Ellen Censky, Rafael de Sá.

SSAR Appointments

Owing to other professional demands, SSAR Secretary John Matter resigned in October 2002. The Board appointed Marion Preest (Claremont Colleges) to complete the remainder of Matter's term of office (through 2004). The Society thanks John for his service to the herpetogical community.

George Pisani has very ably served as SSAR's Webmaster for many years, putting in countless hours to keep the site current. The Society extends its appreciation to George for his efforts. Dennis Desmond, of Alexandria, Virginia, has agreed to become the Society's new Webmaster and will undertake a re-design of the web site.

Robin Jung, of the USGS Patuxent Wildlife Research Center, has been appointed Editor of *Herpetological Conservation*. SSAR thanks outgoing Editor, Steve Corn, who inaugurated the series, as he steps down.

New committee appointments for 2003 include: Ron Brooks, University of Guelph (Nominating Committee); Dawn Wilson, California State University, Chico (Resolutions); John Matter, Juniata College (Conservation); and Ruston Hartdegen, Dallas Zoo (Relations with Herpetologists at Zoological Parks). Congratulations to all.

SSAR to Auction Robert E. Gordon Library

SSAR is pleased to announce that the family of the late Robert E. Gordon (1925–1996), the society's president in 1971, has recently donated his collection of herpetological books and stamps to SSAR. The society intends to auction the individual items beginning in April, with proceeds being used to set up The Robert E. Gordon Endowment for the support of book-length publications.

Gordon was a long-time member of OHS and SSAR and spent most of his distinguished career at the University of Notre Dame where he was professor of biology and eventually vice president. He was a leading specialist on salamander behavior and ecology; he also published on his extensive philatelic interests. A full obituary was published in *Herpetological Review*, 27(3):109–110, 1996.

If you wish to be notified about this auction, contact the SSAR Publications Secretary, Breck Bartholomew, e-mail: ssar@herplit.com, phone/fax: 801-453-0489. The auction will be held on-line on or about April 2003.

NEWSNOTES

Nikolai Orlov Awarded Honorary Doctorate

Göteborg University (Sweden) awarded an honorary doctorate to Russian herpetologist Nikolai Orlov at a ceremony in Göteborg on 19 October 2002. Orlov was nominated for this award by Swedish colleagues Claes Andrén and Göran Nilson, both of whom are professors at Göteborg.

Nikolai Orlov began his herpetological career as a field assistant during expeditions in remote areas of Central Asia. Eventually he took over responsibility for these expeditions, arranging collecting trips to many parts of Asia. Today, he is among the most experienced and capable field herpetologists in the world. He has an impressive knowledge of museum techniques, taxonomy, ecology, and conservation biology. During the last ten years, his field work has centered on the remaining rainforests of Vietnam and surrounding countries. Together with American and Canadian colleagues he has described more than 50 new species of amphibians and reptiles from these areas. He and colleagues are preparing a book covering the amphibians of Vietnam and adjacent areas.

SSAR congratulates Nikolai Orlov on this recognition.

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 29th Annual Meeting at the University of Kansas in Lawrence, Kansas, on 2–3 November 2002. Over 90 participants attended scientific paper sessions to listen to 24 talks by scientists and students from across the nation. Keynote speaker was Dr. Frank T. Burbrink, professor at the College of Staten Island, Long Island, New York. Dr. Burbrink spoke about the diversity of North American snakes.

During the Society business meeting, Nicole Palenske, graduate student at Emporia State University, received the 2002 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas. Chris Hutson, student at Tabor College received the Alan H. Kamb Grant for Research on Kansas Snakes.

At the Saturday night auction and social, John Cavitt, professor of biology at Weber State University, Ogden, Utah, was chosen as the fifth recipient of The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology, based on his paper being chosen as the best scientific contribution published during the years 2000–2001 on native Kansas herpetofauna.

KHS members James Gubanyi and Robin Oldham were recognized as the fourth annual recipients of The Big Croaker Awards, sponsored by the Kansas Department of Wildlife and Parks. Established in 1999, the awards this year were given to those individuals for their efforts in monitoring anuran choruses during the spring of 2002. Each spring, nearly 100 volunteers census choruses of amphibians on eighty 15-mile routes across Kansas, establishing baseline information that will eventually be used to publish a Kansas Amphibian Breeding Atlas.

MEETINGS

Meetings Calendar

18–22 June 2003—Second International Congress on Chelonian Conservation in Senegal. Conference to be held in English w/ French translations. Information: www.tortues.com; e-mail: soptom@soptom.com.

26 June–1 July 2003—46th Annual Meeting, Society for the Study of Amphibians and Reptiles, together with The Herpetologists' League and the American Society of Ichthyologists and Herpetologists. Hotel Tropical, Manaus, Brazil. Details available elsewhere in this issue and from the meeting web site: http://www.aiha.org.br/.

12–16 August 2003—12th Ordinary General Meeting of Societas Europaea Herpetologica, St. Petersburg, Russia. Information: Natalia Ananjeva (e-mail: agama@NA4755.spb.edu).

3–6 September 2003—International Herpetological Symposium, 27th Annual Meeting, Houston, Texas, USA. Information: http://www.kingsnake.com/ihs/index.html.

CURRENT RESEARCH

The purpose of **Current Research** is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, **Eli Greenbaum** or **Omar Torres-Carvajal**; postal and e-mail addresses may be found on the inside front cover.

The current contents of various herpetological journals and other publications can now be found at: http://www.herplit.com/contents.

Colubrid Venom Biochemistry

Nearly half of the species in the polyphyletic family Colubridae produce venom in Duvernoy's gland. Several colubrid species produce venoms that have proven fatal to humans, and the author suggests further study might reveal that additional taxa are capable of lethal envenomations. Studies of colubrid venoms are difficult because of the lack of commercially available venoms and difficulty with obtaining venom samples from snakes with rear fangs and low pressure of venom delivery. Anaesthesia was

used in this study to obtain samples and injections of ketamine and pilocarpine increased venom yields. The author discussed toxicity and biochemistry of numerous colubrid venoms and the purification and identification of venom components. In comparison to viperid or elapid venoms, colubrid venoms are poorly known and additional research is needed.

Systematics of *Cnemidophorus*

The teiid genus *Cnemidophorus* is composed of approximately 50 species that collectively range from the United States to Argentina and occur in numerous habitats. The ecology, life history, and parthenogenetics of this clade have been studied extensively, but the phylogenetic placement of this genus within the Teiidae and corresponding intrageneric relationships have received little attention. The authors examined: 1) whether *Cnemidophorus* is monophyletic; 2) the relationship of this genus to other teiinine genera; and 3) whether the bisexual species groups are monophyletic, and their relationships to each other. Twenty-seven species of *Cnemidophorus* and 14 additional species (41 ingroup taxa) and five outgroup taxa were examined for DNA data (12S and 16S genes), allozyme data (31 protein loci), and ten morphological characters that have been used in previous studies to identify generic and subgeneric species groups in the family Teiidae. These data were combined into a single data matrix and analyzed with PAUP* 4.0b2. Some reweighting of characters was done *a posteriori* and tested with successive approximations. Results indicated: 1) *Cnemidophorus* monophyly is not supported; 2) the North American species groups (*deppii, sexlineatus,* and *tigris*) form a monophyletic clade; 3) *Ameiva* monophyly is not supported; and 4) karyotype evolution is consistent with phylogeny. The genus name *Aspidoscelis* was resurrected to recognize the monophyly of the North American clade. The majority of unisexual species are in the genus *Aspidoscelis;* about a third are parthenogenetic.

REEDER, T. W., C. J. COLE, AND H. C. DESSAUER. 2002. Phylogenetic relationships of whiptail lizards of the genus *Cnemidophorus* (Squamata: Teiidae): a test of monophyly, reevaluation of karyotypic evolution, and review of hybrid origins. American Museum Novitates (3365):1–61.

Airborne Sound Detection in Rattlesnakes

Recent research has indicated that snakes can perceive airborne vibrations more effectively than groundborne vibrations. The authors examined the ability of eight individuals of *Crotalus atrox* to detect airborne sounds in an acoustic isolation chamber. Snakes were recorded during a 30 s control period, 4 s trial period in which sound was played, and a 30 s recovery period. The number of tongue flicks, head jerks, amount of time spent moving, and rattling behavior was recorded from the videotape. During the stimulus period, snakes reduced tongue flicking, became motionless, jerked their heads, and rattled significantly more than in the control or recovery periods. This is the first study to document behavioral responses to airborne sounds in snakes.

Digestive Metabolism in a Python

Snakes undergo exceptional morphological responses to a meal following a fast; intestinal mass can be doubled and brush-border transport capacities can increase rapidly. These morphological changes are associated with an increase of metabolic oxygen consumption, but it is not clear if the morphological changes are directly responsible for the increased metabolism. The authors placed eight juvenile *Python molurus* in individual plastic respiratory chambers for the experiments. Measurements of oxygen uptake and carbon dioxide excretion were taken from the snakes twice a day. The snakes were divided into two groups; both groups had the same fasting periods but they differed in the order of fasting durations. The metabolic responses following feeding were large (21–35% of ingested energy), but these responses were independent of fasting duration. Thus, the increased metabolic rate is not correlated with increased function and growth of gastrointestinal organs.

OVERGAARD, J., J. B. ANDERSEN, AND T. WANG. 2002. The effects of fasting duration on the metabolic response to feeding in *Python molurus:* an evaluation of the energetic costs associated with gastrointestinal growth and upregulation. Physiological and Biochemical Zoology 75:360–368.

Habitats of Stream-Dwelling Amphibians

The authors examined populations of seven amphibian species in second- and third-order streams of southwestern Oregon and northwestern California. Because amphibian biomass can exceed fish biomass in these streams, it is important to understand how variation of habitat use by amphibians is related to natural and anthropogenic disturbance. Study sites were selected to represent a wide range of vegetation types and age of forest adjacent to streams. Numerous statistical analyses were performed on the data to determine: 1) differences in diversity; 2) presence/absence of taxa; and 3) relationships between environmental variables and amphibian density. Amphibian diversity was greater in streams passing through the oldest forest stands. Different environmental variables explained the presence and density of *Ascaphus truei* and *Dicamptodon tenebrosus;* the remaining five amphibian species were too rare to make comparisons. The authors caution that

resource availability, historical biogeography, interspecific interactions, and demographic stochasticities might also explain amphibian presence and density.

Species Isolation in Sea Snakes

A recent resurgence of interest in the potential role of sexual selection on generating speciation in closely related, sympatric species has focused little attention on reptiles. The authors examined this phenomenon in laticaudine sea snakes, *Laticauda colubrina* and the relatively smaller *L. frontalis*, which are not known to hybridize in nature. Over a six-week period, the authors collected adults of both species and observed their courtship behavior in open-topped nylon arenas. Skin lipids were obtained on cloth pieces from female snakes, and male reactions to these samples were recorded. Additional lipid samples were examined from both sexes of both species and analyzed with gas chromatography and mass spectrometry. Arena trials confirmed that the two species exhibit a strong preference for conspecific rather than heterospecific mating. Males of both species directed more tongue flicks at conspecific cloth samples than heterospecific samples, but *L. colubrina* was less discriminating than *L. frontalis*. Biochemical analysis of lipid samples confirmed differences between species and between the sexes within species. The conflicting preference results in male *L. colubrina* might be explained by a preference to mate with larger females.

Mate Choice in *Anolis carolinensis*

When reproductive benefits outweigh the costs of being choosy, males can be associated with mate choice. This sentiment explains the "Coolidge effect," in which males prefer to mate with novel females because the number of inseminated females increases, thus maximizing male reproductive success. Sixteen adult male and 19 adult female *Anolis carolinensis* were collected early in the breeding season and housed in male/female pairs in cages. Pairs of subjects were allowed to acclimate for three days and on the fourth day the pair was videotaped from a darkened blind for 30 min. The resident female was then removed, and 15 min later a female (resident or novel) was introduced into the enclosure. Similar experiments were conducted in the field; novel females were introduced into the territories of males. Males engaged in courtship displays three times more with novel females than with resident females in laboratory experiments. In field trials, males directed ten times more displays toward novel females than resident females in baseline sessions. These results suggest that preference for novel females is a cognitive process in this species.

Life History of a Madagascan Frog

The genus *Boophis* consists of numerous species of rainforest treefrogs; the *Boophis albilabris* Group is one of the most poorly studied in this genus. The authors studied the vocalizations, tadpole morphology, and skeletochronology of *B. albilabris occidentalis* at Berara Forest and vocalizations of *B. albilabris* at Anjaharibe-Sud, Madagascar. Morphology, mating behavior, vocalizations, and color of adults were contrasted between the two populations. Lines of arrested growth in the periosteal bone of *B. a. occidentalis* were described; age estimates placed one individual at 11 years. Based on bioacoustic data, keratinized dermal structures, body size, and webbing, the authors recognized *B. occidentalis* as a distinct species. The authors hypothesized that *B. albilabris* and *B. occidentalis* secondarily returned to a discontinuous reproductive activity with breeding aggregations.

ANDREONE, F., M. VENCES, F. M. GUARINO, F. GLAW, AND J. E. RANDRIANIRINA. 2002. Natural history and larval morphology of *Boophis occidentalis* (Anura: Mantellidae: Boophinae) provide new insights into the phylogeny and adaptive radiation of endemic Malagasy frogs. Journal of Zoology, London 257:425–438.

Molecular Systematics of *Thamnophis*

The garter snakes of the genus *Thamnophis* include approximately 30 species of colubrid snakes, including some of the most intensively studied snakes in the world. The authors obtained samples from 29 species of *Thamnophis, Adelophis foxi,* and four outgroup species. A total of 3809 bases were sequenced from each sample, representing complete mtDNA sequences of cytochrome *b,* NADH dehydrogenase 1 and 2, and half the sequence of NADH dehydrogenase subunit 4. Maximum parsimony and maximum likelihood analyses were conducted (PAUP* 4.0b) on the four genes separately and combined. All analyses placed *Adelophis* and *Thamnophis validus* (= *Nerodia validus*) within the genus *Thamnophis*. Bootstrap analyses of maximum parsimony trees did not identify conflict between any two genes; the combined data tree resolved 28 of 30 possible clades within *Thamnophis*. The combined maximum likelihood tree of all four genes resulted in a phylogeny that had four differences from the maximum parsimony tree, but none of the relationships conflicted with clades that had moderate or strong support from bootstrap values. Biogeographic hypotheses are discussed for Mexican clades. The authors also evaluated whether the support for clades reached a plateau with an increasing number of characters.

Molecular Systematics of Dwarf Boas

The Tropidophiidae includes about 21 species of New World snakes in four genera. The relationships of these snakes within the family and to other families is not well resolved because of considerable disagreement about the relationships of basal snake lineages. The authors tested three previously proposed hypotheses: 1) the Ungaliophiidae clade (*Exiliboa* + *Ungaliophis*) is not closely related to the Tropidophiidae clade (here including *Trachyboa* + *Tropidophis*); 2) the latter clade is sister to Caenophidia; and 3) Ungaliophiidae is part of a monophyletic Booidea. The authors sequenced 1.9 kb of mtDNA (12S, 16S, and intervening valine t-RNA genes) from 23 species of snakes representing most major snake lineages and all four genera of dwarf boas. Aligned sequences were analyzed in PAUP* 4.0b8 with maximum likelihood; branch support was assessed with bootstrapping and Bayesian analysis. A single best tree indicated that dwarf boas are not monophyletic. Support was found for a clade including *Trachyboa* + *Tropidophis*, and another clade of *Exiliboa* + *Ungaliophis*. The former group was rejected as the sister taxon to Caenophidia, and the monophyly of Booidea was not supported. Bayesian support values estimated true probabilities of recovering respective clades more accurately than bootstrap values. One consequence of this phylogeny is that relatively kinetic skulls emerged early in snake evolution, and secondary reductions in skull flexibility occurred in fossorial lineages.

OBITUARIES

Herpetological Review, 2003, 34(1), 6–8.

Garth Underwood (1919–2002): A Vision of Reptile Systematics

ROGER S. THORPE
School of Biological Sciences, University of Wales, Bangor
Gwynedd LL57 2UW, UK
e-mail: bss024@bangor.ac.uk

Garth L. Underwood, the systematic herpetologist, died in the early hours of the morning on the 15 October 2002 after a brief spell in hospital. He was 83 and still making a useful contribution to the area that so fascinated him (Underwood 2002). Garth was much loved by those who knew him and he will be deeply missed, both as a herpetologist and as a friend.

Garth was born in Isleworth, Middlesex, after the First World War (16 July 1919), the eldest son of the renowned artist Leon Underwood and Mary (nee Colman). He went to University College London in 1938, but was conscripted into the Army (Royal Engineers) on the outbreak of World War II in 1939. He must have had an unpleasantly active first part of the war and was a survivor of Britain's worst maritime disaster. He was in France as part of the British Expeditionary Force after Dunkirk. In June 1940 the troopship (*HMT Lancastria*) on which he was returning to England was bombed and sunk off St Nazaire, Brittany with massive loss of life (estimated by some to be around 5000; see http://www.bbc.co.uk/history/war/wwtwo/lancastria_1.shtml). Garth described to me the bravery of his comrades who could not swim as the ship finally sank under them. Later in the war (1943) he went to India where he had an "intelligence" role. He helped develop a system to play sounds of tank battles in the jungle to amuse the Japanese. He kept the secrecy he was sworn to until, to his amusement, he saw it described in all its bizarre detail on a television program. India had a very considerable impact on Garth. It was there where his interest in zoology focussed into an interest in reptiles, where he started publishing, and where he met his wife Molly.

He continued his studies at UCL after the war (1946), being taught by the eminent geneticist J.B.S. Haldane. He took a First Class Honours in zoology (Special genetics), with subsidiary pure mathematics, in 1948. He chose pure mathematics because he could spend the least time on it, and hence more time on zoology.

After graduating Garth took the post of Demonstrator in Zoology at what was the University College of the West Indies at Jamaica, and what later (1962) became the University of the West

Indies. He was rapidly promoted through the system from Demonstrator to Assistant Lecturer (1949), Lecturer (1953), and Senior Lecturer (1958). Garth did not do a PhD, but submitted his publications in 1960 to the University of London, for which he was awarded a DSc for his " Systematic and evolutionary study of reptiles." In 1960 he also became Professor of Zoology in the Faculty of Agriculture, University of West Indies, Trinidad. He served as Dean of that Faculty from 1961 to 1963. During his time in the West Indies he maintained an association with the Museum of Comparative Zoology, Harvard University.

Garth decided to return to Britain for his daughter's education, and in 1964 he took the post of Principal Research Fellow at the British Museum (Natural History) in London, now the Natural History Museum (NHM). After his temporary fellowship at the museum (1964-67) he took the post of Senior Lecturer and later Principal Lecturer at what was Sir John Cass College and later became the City of London Polytechnic (currently London Metropolitan University). Although he retired from the City of London Polytechnic in 1984 he was still actively researching and was based in the Natural History Museum in London. Initially, this was an informal arrangement, but he was recognized as an Honorary Research Fellow in the Natural History Museum in 1994. He continued to work in the museum and inspire his younger colleagues until his death.

Garth's publications extend across seven decades (1945–2002). In general, his work has been marked by its lasting value rather than by a large volume of ephemera. For example, both Garth's original 1959 publications on anole evolution (Underwood 1959; Underwood and Williams 1959) and his 1967 work on snake classification (Underwood 1967) are still heavily cited in this millennium. The early 1950s saw three major contributions from Garth. His influential work on the evolution of reptilian retinas, inspired by G. L. Walls (1942), was published in *Nature* (Underwood 1951), as was his work on gecko taxonomy and evolution (Underwood 1955). Moreover, in this period he and Angus Bellairs developed their ideas on the fossorial origin of snakes (Bellairs and Underwood 1951). To my mind this remains the benchmark paper, and only convincing hypothesis, for the origin of snakes. Garth's interest in reptilian retinas continued through the next two decades (Underwood 1966, 1968, 1970) and an appreciation of their role in snake systematics, as expressed in his classic work "A Contribution to the Classification of Snakes," endured (Underwood 1967a,b, 1997).

Later on in the 1950s Garth worked on legless lizards (Underwood 1957a,b) and the West Indian fauna (Underwood 1957c, 1959, 1964; Underwood and Williams 1959). His work on Lesser Antillean anole series proved to be of enduring importance. His interest in the West Indian herpetofauna continued, with publications on Lesser Antillean snakes until 1999 (Underwood 1993; Underwood et al. 1999).

Garth pioneered a multiple evidence approach to snake systematics, advocating the use of a wide range of morphological features from visual cells, through oesteology to rictal glands. He used his Fellowship at the museum (1964–67) to develop his ideas in this area. This formed the basis of "A Contribution to the Classification of Snakes" as well as later papers (1967b, 1997, 1999), and his last paper (Underwood 2002) was on a morphological system (rictal glands) that may give evidence for snake relationships. A more quantitative approach to taxonomy was developing around the time of Garth's museum fellowship and Garth saw this as complementing his multiple evidence approach. He learned to program a computer and wrote his own programs to pursue his ideas. He was still working on programming compatibility analysis in his later years.

Garth was a committed and dedicated teacher, publishing papers on biological teaching in *Nature* and elsewhere (Underwood 1963). He was also a conscientious administrator acting as Dean in the University of West Indies and as Head of Department in the City of London Polytechnic for a while, at a time of great transition for that Institute. I think it is fair to say that he saw administration as something that was necessary, rather than a reward in itself, and when I knew him he was most fulfilled by museum research. What little time for research his teaching in London allowed was generally spent in the museum looking at specimens. This is what he loved most and his association with the Natural History Museum lasted from his Fellowship until he died, irrespective of whether he was employed elsewhere or retired.

At the time Garth was working in London, one could be forgiven for thinking that Garth was only interested in museum studies and had little interest in fieldwork. However, this was not really the case. Garth's time in the West Indies was a period when he was able to undertake fieldwork, not only in Jamaica and Trinidad, but also throughout the Eastern Caribbean islands, and he took full advantage of this. Garth's description of his first experiences of Dominica, catching numerous *Alsophis* snakes within walking distance of the capital Roseau contrasts with my current experiences, even though these areas have been less impacted by development than some. Garth then did no fieldwork after leaving the West Indies until after the death of his wife Molly. The loss of Molly, to whom he was entirely devoted, was a severe blow to Garth. After being widowed, he recovered an interest in fieldwork and, in spite of advancing years and health problems, he made a series of adventurous trips. In 1998 he visited southern Africa collecting snakes and in 1999, at the age of 80, he went on an expedition to the Crocker Range in Sabah, Borneo. He later visited his old territory of Trinidad and Tobago, taking his grandchildren with him, and his last trip was to attend the 2002 ASIH/HL/SSAR meeting in Kansas City.

Garth was well respected as a herpetologist. He was made an Honorary Member of The Herpetologists' League in 1978 (one of only five), he had numerous species and a genus named after him, and the 1997 "Venomous Snakes, Ecology, Evolution and Snakebite" volume (edited by R. S. Thorpe, W. Wuster, and A. Malhotra) was dedicated to him. Currently, The Natural History Museum is preparing a special issue of the *Bulletin* in his honor, and a retrospective will soon appear in *Copeia*. Sadly, the latter two will now be posthumous.

Garth's achievements may explain why he was a respected herpetologist, but they do little to explain the enduring loyalty of his students or the affection with which he was held. For this one needs to understand Garth's character. Garth had his gentle, and entirely unaffected, eccentricities. I first met Garth 35 years ago when I tried to convince him he should take me on as a PhD student once I had graduated. This was at the stage at which his Museum Fellowship had just ended. The pre-meeting telephone calls had led me to expect a much older man, but Garth was still in his

forties at this time. He came across as someone with some old mannerisms, but with a youthful, quick, and flexible mind, readily open to new ideas. This open, flexible mind stayed with him throughout and he was always very receptive to new ideas, even when they contradicted his own. He was, for example, very complimentary about the hypothesis of a marine origin for snakes.

I used to see Garth when he came into the museum for his weekly dose of research. There was a constant flow of notable researchers through the museum that Garth would delight in meeting, but he always took time to talk to encourage those that were starting out their academic journey. A very young Harry Greene (yes, even Harry was young once) turned up one day from his military posting in Germany to talk about his tail display-injury hypothesis. Harry was dressed smartly, with a severe military haircut, and bristling with respect for authority. However, Garth, in spite of (or perhaps because of) his own time in the military, was entirely non-authoritarian and non-status orientated in his approach to everything and everyone. Harry must have used the address "Sir" more times than I had heard since my schooldays. In spite of being nonplussed by this, Garth soon got Harry to relax, address him as Garth, and have a sensible conversation about bite marks on sand boas' rears.

He was a great teacher, not just directly, but also by example. He always expected the best possible effort in everything and impartial objectivity when considering evidence. The flow of visitors gave plenty of opportunity to air various viewpoints. His approach to academic debate was completely non-confrontational, and when faced with overconfidence he could be crushingly reasonable. Garth was an excellent model: un-opinionated without being opinion-less, open-minded without being mindless, and highly principled without being a prig. It reflects our limitations, and not Garth's, if we were not always able to learn from him. He cared about doing and publishing good science, and providing quality teaching. He never mentioned the paraphernalia of "citation rates," "grant capture," and "quality assurance" that so burden academia, and are so loved by those who administer because they can no longer do. Such a person was not always well-adapted to life in today's academia, but Garth was almost entirely free from cynicism. He enjoyed herpetology, he enjoyed systematics, he enjoyed teaching, and he enjoyed talking to others and encouraging them.

His daughter Vivienne, an architect, survives Garth. We extend to her our congratulations on having such a father and deepest sympathy for the loss.

Acknowledgments.—I would like to thank Vivienne Hughes and Mark Wilkinson for their communications regarding this obituary, and acknowledge Garth for his initial PhD supervision and 35 years of friendship and advice.

Zoo herpetologist and conservationist Sean McKeown passed away on 11 July 2002, at age 58. Born on New Year's Day, 1944, in Los Angeles, California, he spent his early childhood in western Pennsylvania, roaming the woods in search of salamanders, lizards, and snakes. He returned to California to finish elementary and high school. Sean attended the University of California at Santa Barbara, graduating in 1967 with a bachelor's degree in political science. Two years later, he started graduate school at California State University, Chico, where he was a teaching assistant to Frank Cliff. He received his master's degree "with distinction" in 1973, in a combined biological sciences/anthropology program. The title of his thesis was "An Analysis of Protective Attitudes Concerning the Puma (*Felis concolor*)."

In 1975, Sean moved to Hawaii shortly after receiving his master's degree and began working at the Honolulu Zoo. Surprisingly, his zoo experience had been minimal and was limited to a yearlong stint at the Los Angeles Zoo prior to starting graduate school. Sean brought from California his most cherished possessions, a collection of Chumash Indian baskets and an immaculate, red and white 1955 Chevy. Always proud of his Irish heritage, he kept a large, iron-hard shillelagh hanging in the kitchen of his Diamond Head home.

While in Hawaii, Sean helped acquire a significant collection of reptiles at the Honolulu Zoo, emphasizing captive breeding of endangered species. Before his arrival, the few reptiles on display included green iguanas, American alligators, and Galapagos tortoises, the latter being part of an important captive breeding program. The zoo's 'Animal Lanai' featured a miscellaneous assortment of small animals, the highlight of which was a male red rat snake. Snakes are illegal in the state and the snake enclosure was made possible only through special permission of the Hawaii State Government after extensive petitioning by the zoo-going public. According to Assistant Zoo Director Tommy Higashino, Sean wasted no time in transforming the Animal Lanai into a full-fledged herpetarium. The zoo visitor was then treated to such exotics as green basilisks, matamata turtles, and lace monitor lizards.

More than anything else, Sean wished to instill in the people of Hawaii a healthy respect and appreciation for reptiles and amphibians. Once, at a convention for a well-known clothing manufacturer whose trademark was an embroidered alligator, Sean and reptile keeper Duane Meier offered to bring a live alligator to the exclusive Honolulu Club as a promotion. In exchange, a $50 donation was promised for use in the reptile house. The event was held on the second floor, so imagine the surprise of those attending the convention when the elevator door suddenly opened and two men tethering a 6-foot alligator entered the room!

Soon after his arrival in Hawaii, Sean turned his attention to the study of the local herpetofauna, wishing to expand on earlier published accounts by Stejneger (1899. Proc. U.S. Natl. Mus. 21:783–813), Snyder (1919. Proc. U.S. Natl. Mus. 54:19–25), Oliver and Shaw (1953. Zoologica 38:65–95), and Hunsaker and Breese (1967. Pac. Sci. 21:168–172). In his first book, *Hawaiian Reptiles and Amphibians* (Oriental Publishing Co., 1978), Sean worked with local photographer Grant Uchida to produce some amazing close-up photographs of the various introduced Pacific geckos and skinks. In 1996, a revised and much expanded version of the book was published.

Between 1980 and 1981, Sean traveled to the Indian Ocean in pursuit of his favorite herpetological passion, the geckos of the genus *Phelsuma*. Granted special permission by the Republic of the Seychelles' Department of Conservation, he visited the islands of Mauritius and Reunión, where he conducted behavioral studies on numerous species. As a consultant to the Seychelles government, Sean also designed and supervised the construction of an egg incubator for the captive propagation of the Aldabra giant tortoise (*Geochelone gigantea*).

In 1983, Sean and his zoo staff successfully bred the critically endangered Madagascar angulated tortoise (*Geochelone yniphora*). In recognition of this achievement, the Honolulu Zoo received the prestigious Edward Bean Award for conservation, presented by the American Association of Zoological Parks and Aquariums (now the American Zoo and Aquarium Association). Later that year, Sean left Hawaii and returned to California, where he accepted a position as Curator of Reptiles at the Chaffee Zoological Gardens in Fresno. In 1986 another AZA award was received for the captive breeding of the Madagascar ground boa (*Acrantophis madagascariensis*).

Bitten again by the travel bug, Sean was off to hunt geckos in 1987. Supplied with wildlife permits from the government, he went in pursuit of the New Caledonian giant geckos (*Rhacodactylus*). Later that year, Sean was granted permission by the New Zealand Department of Conservation to study the endemic geckos of the genera *Heteropholis* and *Naultinus*. On one of his last overseas trips, he visited the island of Aruba in the Caribbean. As a member of the AZA's Species Survival Plan, he assisted with the collection of data on the Aruba Island rattlesnake (*Crotalus unicolor*).

In 1990, Sean became the managing editor for the American Federation of Herpetoculturists' magazine, *Vivarium*. He was also a contributing author. In the spring of that year, The First International Symposium on Turtles & Tortoises: Conservation and Captive Husbandry convened at Chapman University in Orange, California. Sean was instrumental in helping to organize the conference and assisted with editing the symposium proceedings. Dur-

ing this period of extracurricular activity, he continued his work at Chaffee Zoological Gardens until 1995, when he took an early retirement to concentrate on his writing. These efforts resulted in the publication of *The General Care and Maintenance of Day Geckos* (1993), *Jackson's Chameleons* (*In:* Care and Breeding of Panther, Jackson's, Veiled and Parson's Chameleons, 1995), *General Husbandry and Management* (*In:* Reptile Medicine and Surgery, 1996), *A Field Guide to Reptiles and Amphibians in the Hawaiian Islands* (1996), and *The General Care and Maintenance of Tokay Geckos and Related Species* (1997). An avid history buff, Sean also enjoyed interviewing well-known zoo herpetologists for a "People Profiles" feature in *Reptile & Amphibian Hobbyist*.

In 1996 Sean was diagnosed with idiopathic cardiomyopathy, or congestive heart failure. Three years later he received a left ventricular assist device that artificially kept his heart functioning. This experience made Sean a strong advocate of organ donation. In April of 2000, he received a heart transplant at Stanford University Medical Center.

Until the very end of his life, Sean continued his involvement in several conservation committees, including the IUCN's Captive Breeding Specialist Group and Tortoise and Freshwater Turtle Specialist Group. He also served as a consultant to Hawaii's State Department of Agriculture, striving to keep the brown tree snake (*Boiga irregularis*) and the coquí común (*Eleutherodactylus coqui*) from becoming established in Hawaii. He continued to conduct surveys on the endangered blunt-nosed leopard lizard (*Gambelia sila*) for the California Department of Fish and Game and wrote a monthly column for *Reptiles* magazine entitled "Ask the Breeder" (he was also a regular contributing author). Sean enjoyed teaching young people about natural history and assisted students with their science fair projects. He was also a judge at the California State Science Fair.

Sean is survived by his wife, Wendy and two daughters, Dorie and Casey. "The country has lost one of its most brilliant, hardworking and active leaders in wildlife conservation of this era. We will dearly miss him," said Paul Breese, former director of the Honolulu Zoo.

We will, indeed, miss you. Aloha, Sean.

ZOO VIEW

Since 1976, George B. Rabb has been Director of the Chicago Zoological Park, also known as the Brookfield Zoo. George anticipates retirement after many years of professional service to the zoo and conservation community. He began his career as research coordinator at the Zoo in 1956. As former Chairman of the Species Survival Commission (SSC) of IUCN-The World Conservation Union beginning in 1989, he formed and supported the Declining Amphibian Populations Task Force (DAPTF) under the banner of IUCN. For his accomplishments, he was awarded the Peter Scott Award in 1996 by SSC.

George's herpetological research has been impressive. In 1955–1956, he described new salamanders from Mexico and the tadpole of *Hyla robertsorum*. The next year, he named a new race of iguanid lizard (*Leiocephalus carinatus granti*) from Cayman Brac, B.W.I. The same year, George and E. B. Hayden recorded the history of the Van Voast-American Museum of Natural History Bahama Islands Expedition and outlined general features of the Islands. In 1959, George described a new frog of the genus *Plectrohyla* (*P. pycnochila*) from the Sierra de los Tuxtlas, Mexico. With his colleague Hymen Marx at the Field Museum of Natural History in Chicago, George produced a series of seminal papers on snake evolutionary biology. He studied the viperid snake *Azemiops* and compared its cephalic anatomy and phylogenetic position relative to Viperinae and Crotalinae. In 1965, a paper on relationships and zoogeography of the viperine snakes appeared. He investigated morphometrics of the ectopterygoid in advanced snakes (Colubroidea). In 1970 and 1972, two major papers on character analysis of advanced snakes were published. In another, two colubrid snake genera convergent to the vipers (*Pythonodipsas* and *Spalerosophis*) were treated. Rabb published a number of important papers, some with his wife Mary, on amphibian reproductive behavior, based in part on their zoo colony of pipid frogs. For his contributions to the herpetological community, he was elected President of the American Society of Ichthyologists and Herpetologists.

Rabb believed that zoos must change from menageries to conservation and research centers; he wrote many papers on this topic. George and his staff have developed protocols for successful captive management programs, such as designing techniques for surveying and maintaining genetic diversity in zoo animal colonies. George was instrumental in establishing the International Species Information System (ISIS), the inventory listing of captive animal populations which is crucial in providing data to ensure proper pairings of potential breeders and monitoring the population structure.

As a measure of the esteem and respect that he engenders from his colleagues, his career and contributions to zoo biology and conservation have been covered in full in a recent book (Ross, A. 2001. Rabb, George B. 1930– American director of the Chicago Zoological Park. *In* C. E. Bell [ed.], Encyclopedia of the World's Zoos, pp. 1035–1037. Fitzroy Dearborn Publishers, Chicago and London).

George and Hy Marx were important mentors for me during my early years in Chicago. By their example, I learned how herpetology should be approached in a careful and systematic manner. For their friendship, inspiration and guidance, I am eternally grateful.

Recently, approximately 10,000 Asian turtles and tortoises were confiscated in Hong Kong, destined to be used for food and medicinal purposes in China. The chelonians were in deplorable condition, requiring medical evaluations and extensive care before they were fit to be sent to European zoos and other facilities. Curator Gerard Visser from the Rotterdam Zoo oversaw the maintenance of many of these creatures, arranged homes for them, and coordinated shipping, which was no easy task. Gerard demonstrated how important one individual in the zoo community can be when faced with a crisis of this magnitude.

Because the herpetological history of his Zoo is so important, I asked Gerard to write the following article. He took on this project seriously, spending hours in the zoo archives where he unearthed materials long hidden. My hope is that others will find his account as fascinating as I did.

—James B. Murphy, Section Editor

Herpetological Review, 2003, 34(1), 11–16.

Herpetology at the Rotterdam Zoo

e-mail: g.visser@rotterdamzoo.nl

The Old Rotterdam Zoo: 1857–1940

The Rotterdam Zoo was founded in 1857, and one of the oldest sources available (Van Bemmelen 1869) shows that reptiles were already represented in the collection. The next year the animal collection consisted of 204 mammals, 659 birds, and 29 reptiles, called "creeping animals" in this report (Fig. 1).

I was unable to discover exactly how and where the reptiles were housed before 1906. The minutes of the "Buildings-committee" of 4 June 1902 show that the decision was made to demolish and rebuild the "winterbuilding" which housed not only reptiles and amphibians during the winter but also those mammals and birds requiring heated houses or stables. Porcupines and snakes are specifically mentioned as residents. In the minutes of 16 November 1904 the Director questioned whether a new reptile building was really necessary for the Zoo. In response to his query, the entire committee decided that a new facility was needed, but that it should not be built too cheaply. This new building cost 35,400 guilders (approx. US $17,000) and construction started in 1905. Zoo herpetologists will be pleased to learn that when a reptile keeper was to be hired for the new Reptile House, the Director in July 1905 (again meeting with the Buildings-committee) claimed: "This is a difficult and complex position. Mr. Winde, a florist, is an educated person, and has even published in magazines. He should therefore be paid better wages than *common* keepers. And only one woman to clean the windows in that building (!)" The Zoo board later rejected the extra salary (again, not surprising to-

1 Groote Ikstern of Kaugek....	Sterna cantiaca, *Gmel.*
7 Landschildpadden...........	Testudo.

FIG. 1. The 1858 list of zoo specimens contained 7 tortoises (*Testudo*), 4 terrapins (*Emys*); 3 seaturtles (*Chelonia*), 1 African crocodile (*Crocodilus vulgaris*, Cuv.); 1 crocodile from Borneo (*Gavialis schlegelii*, S. Müll.), 2 Caimans (*Alligator lucius*, Cuv. *s. mississippiensis* (Daud.)); 4 sawa-snakes from Java (*Python bivittatus*, Kuhl); 3 Boas (*Boa constrictor*, Linn.); 1 glass snake (*Natrix torquata*, Merr); 2 lizards (*Lacerta stirpium*, Daud.); 1 giant salamander from Japan (*Sieboldia maxima* (Schleg.).

day), but Mr. Winde was allowed to go to the Amsterdam Zoo "Artis" to learn to care for reptiles.

The new Reptile House opened in 1906 (Fig. 2). This house was famous for its central crocodile pond, where a large group of crocodiles could be observed at close range. At first, this exhibit was a barren pool measuring 12 x 6 m with a central concrete island (Fig. 3). In 1915 one of the entries in the "Book of Gifts to

FIG. 2. Exterior of the Reptile House, 1906.

GEDRANG OP DE ZANDPLAAT OP EEN HEETEN ACHTERMIDDAG

FIG. 4. The Crocodile Pool after 1915, with added rockwork.

the Zoo" reads: "A donation of one hundred guilders to embellish the Crocodile Pool in the Reptile House with rockwork." We can therefore safely assume that photographs showing the (very pretty!) rockwork in the Crocodile Pool date from after 1915 or 1916 (Fig. 4). In the left wing of the house large cages for boids could be found; in the right wing, larger varanids, teiids, and iguanids were exhibited. Along the walls of both wings, medium-sized and small terrariums and aquariums were installed for smaller reptiles, amphibians, and fishes. Along the extreme left wall, behind a glass screen, was the enclosure for giant tortoises. These animals had access to an outside pen on warmer days. During the winter they were allowed to wander around parts of the public area of the house. Along the far right wall there was a large aquarium (initially intended to house a seal!) which contained large indigenous fishes, like catfishes and pikes.

Many of the reptiles were brought to the Zoo by the masters and crews of the Dutch commercial fleet. Rotterdam was already a major seaport at the time, and these ships brought back animals from their runs to the Dutch overseas colonies in the East Indies (now Indonesia) and West Indies (Netherlands Antilles). Often ship owners instructed their captains to bring animals for the zoo. Many owners were members of the Rotterdam establishment who regularly gathered in the Zoo's famous Society Building and that group supported the Zoo in many ways. In fact, Board members were usually selected from their ranks.

The great majority of reptiles brought to the Zoo were acquired in the East Indies. The *Javaansche Sawah slang* (Javan ricefield snake) was one of the commonest species to be presented to the Zoo. Or rather the two most common species, because at the time both *Python reticulatus* and *Python molurus bivittatus* were called *Sawah slang* in Dutch. Other species that were commonly presented to the Zoo were: green seaturtle (*Chelonia mydas*), Amboina box turtle (*Cuora amboinensis*), and water monitor (*Varanus salvator*). In some cases, these reptiles were sold to other zoos in Europe. The names of the zoos in London, Frankfurt, Leipzig, Berlin, and Antwerp appear regularly in these old records[3].

Many reptiles were short-lived, green iguanas (*Iguana iguana*) often not lasting much longer than four weeks (Van der Werff, pers. comm.). The seaturtles were housed in the already overcrowded crocodile pond. They must have had a very unpleasant life and presumably did not live very long.

Although a number of well-respected zoologists were employed

at the Zoo over the years (Kuiper, Van Bemmel, Appelman) none of them specialized in reptiles. Probably the most famous scientist to become director of the Zoo was Dr. Johann Büttikofer (1850–1927), the Swiss-born naturalist who was appointed assistant to the director of the Leiden Museum, Prof. Schlegel, in 1878. Büttikofer became an authority on West African wildlife after major expeditions to Liberia in 1879–1882 and 1886–1887. After completing his account of these travels (Büttikofer 1890–91) he was invited to join a large zoological expedition to Central Borneo. Meanwhile, in 1883, he had become curator of the Leiden Museum Bird Collection. Four years later, he became director of the Rotterdam Zoo; his appointment was a significant event for the Zoo as Büttikofer was one of the most respected scientists of that period. Many taxonomists named West African fishes, birds, and mammals in his honor. Büttikofer's main interests were birds and mammals, but in volume 2 of his books on the Liberian expedition, he covered reptiles and amphibians (Büttikofer 1890:434–447); his accounts were accompanied by black-and-white drawings of a leatherback turtle (*Dermochelys coriacea*), a Nile crocodile (*Crocodylus niloticus*), a slender-snouted crocodile (*Crocodylus cataphractus*), a broad-fronted crocodile (*Osteolaemus tetraspis*), and a delightful color plate of the Rhinoceros viper (*Bitis rhinoceros* Temminck; = *Bitis gabonica rhinoceros* Schlegel) (Fig. 5). He retired from the Zoo in 1924 at age 74, and returned to Switzerland. Van Bemmel, director of the Rotterdam Zoo from 1961 until 1969, published a short essay on Büttikofer, including a photograph of him during his expedition in Borneo (Van Bemmel 1959)

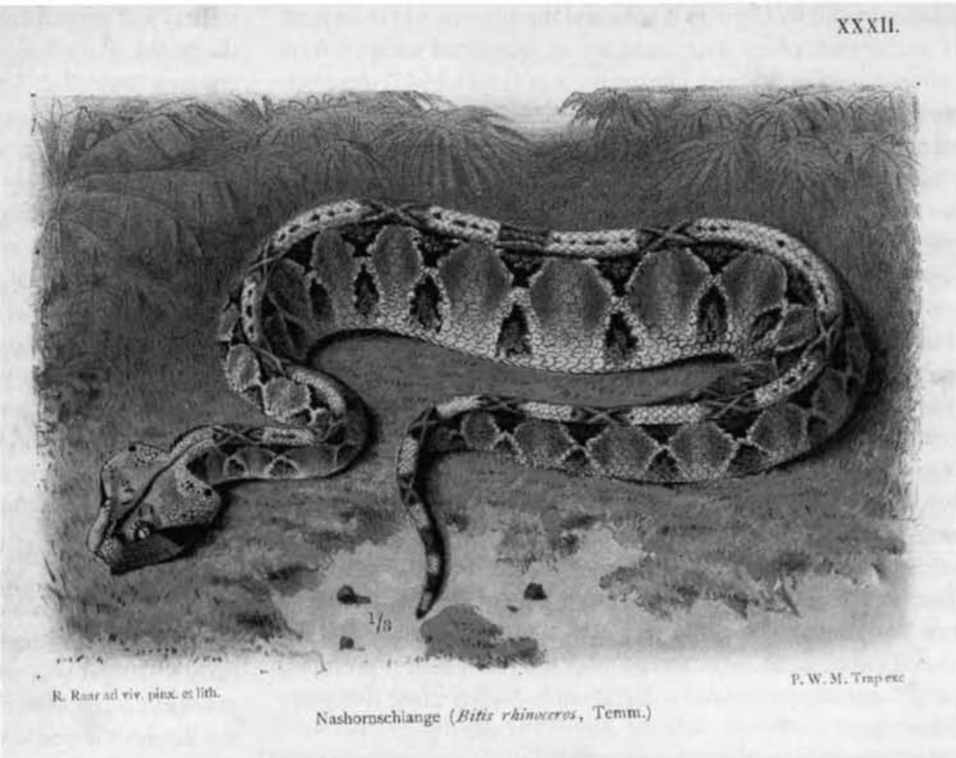

FIG. 5. Büttikofer's 1890 color plate.

Because trained herpetologists were unavailable, not all animals were always identified correctly; for example, in one of the old guide-books a photograph of a tuatara (*Sphenodon punctatus*) is shown and called "green iguana" (Fig. 6). I also found a picture of a Komodo dragon (*Varanus komodoensis*) (Fig. 7) in the old reptile house—so it must have been living in the Reptile House sometime between 1906 and 1940, but so far I have been unable to find any reference to it in the records!

The New Zoo (Diergaarde Blijdorp): 1940–1974

Because the city was growing the zoo had to move from the town center in 1940 to make room for developments. Architect Ir. Sybold van Ravesteijn was given the assignment to design a new zoo, and perhaps typically, an actual reptile house was not included in that plan. Birds and reptiles were housed in the same building, a tropical house that formed one of the two wings of the *Rivièrahal* (Rivièra-Hall) in the heart of the new zoo. Only a few cages in the central area of that tropical house were reserved for reptiles, and probably because of the popularity of the crocodile pool of the old zoo, a large part was reserved for crocodilians. In May 1940 the

FIG. 6. Tuatara, falsely identified as a "groene leguaan" (green iguana).

FIG 7. Komodo dragon in the old zoo.

old zoo was hit by German bombs and the animals had to be hastily transferred, often after recapture as many had escaped from their damaged enclosures. During the war (1940–1945) there was a great shortage of food and other basic needs, and many of the cages could not be heated. Therefore, many reptiles died, and among the reptiles that had lived in the old zoo's Reptile House that survived were—not surprisingly—a pair of American alligators (*Alligator mississippiensis*) and slender-snouted crocodiles (*Crocodylus cataphractus*).

To my surprise, I have been able to find only three photographs of that early period from 1940 to 1954. One shows four heads of adult American alligators (Moerkerk, undated, c. 1950) and another shows the crocodilian exhibit which housed them just after completion, in a book on the architecture of Van Ravesteijn (De Vries 1986). The third photograph pictures nine keepers holding a very large python in front of the new crocodile pool, published in the Zoo's magazine *Blijdorp Geluiden* to accompany a general article on snakes (Appelman 1958). This lack of historical documentation might signify that the popularity of reptiles reached a very low level just after the war. Was this an indication that the general public (and, who knows, also the zoo's staff?) preferred "nicer," cuddlier, and more colorful animals after those five years of hardship?

However, the need for more reptile displays was evident very soon after 1950. It is likely that visitors remembered the old reptile house with its strange and sensational creepy creatures and the zoo staff became aware that a reptile house, even if small, was in high demand. In 1954 one of the two tea-houses was modified into a legitimate reptile house. It opened on 15 April of that year. The reptile cages in the central tropical house became aviaries for birds and in the new Reptile House several large, but somewhat barren, enclosures (Fig. 8) were made for large monitors, common boas, large pythons, iguanas, spectacled caimans, seasnakes, seaturtles, one giant tortoise, and some venomous snakes —and of course two pools for the above -mentioned four crocodilians. This house became the realm of head keeper Joop van der Werff who worked there until 1974. The house had a great tropical atmosphere because of the high humidity and a wealth of tropical plants. Van der Werff added smaller cages for lizards, snakes, turtles, and amphibians along the outer walls. Over the years he decorated all the larger cages and modified them into more modern type "habitats." Again, no true curator was appointed and Van der Werff worked under the supervision of overseer of keepers Pierre van Leeuwen, who was also responsible for the birds and fishes and indeed was content to redirect most of the reptile work to Van der Werff. Hardly any reproduction took place, except for some live-bearing species such as *Boa constrictor* and a notably large brood of 55 Gaboon vipers (Van der Werff 1970).

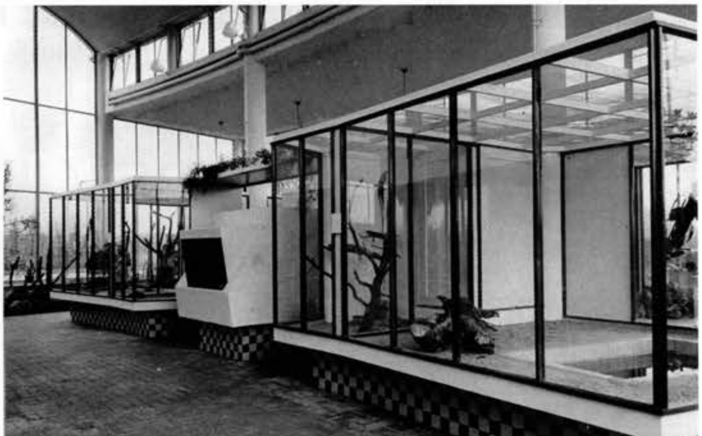

FIG. 8. The interior of the reptile house in the new zoo (1953). It closed again in 1974.

The first scientist with a real interest in reptiles was staff biologist Dr. Hans van Roon, and he incorporated a more systematic approach in keeping and breeding reptiles around 1970. His approach resulted in the first hatching of green iguanas in the Zoo (van Roon 1976) and in a more interesting, diverse collection of reptiles. When I joined the zoo in 1972 I was hired by van Roon as a fish keeper; I got my first training as a reptile keeper by Van der Werff in 1973.

The Rivièrahal as Reptile Center: 1974–c. 2002

After Zoo Director Dick van Dam had been appointed in the early 1970s, it was soon decided that ectotherms should play a more important role in the animal collection of the zoo and that the Rivièrahal would be the central place for fishes, amphibians, and reptiles[3]. Additional staff were hired, but van Roon's successor, Han Assink, although the first person to get the curatorial position, still had to oversee the birds and fishes, as well as reptiles. As in the old days, much of the reptile work was done by the keeping staff, but this time a real curator was available, who was much more actively involved in the herpetological collection than any of his predecessors. In the Rivièrahal more and more terrariums were constructed, and in 1976 a new Crocodile Wing was added. The four large crocodilians, by now in Rotterdam for over 50 years, were moved to new quarters, this time more spacious than ever before[3]. In the same building, spectacled caimans (*Caiman crocodilus*) and a large pair of water monitors were exhibited.

In 1979 the Amazonian Wing was added to the Rivièrahal, and here mainly large osteoglossid fishes were housed in a pool surrounded by Amazonian vegetation. Reptiles exhibited here were red-footed tortoises (*Geochelone carbonaria*), South American giant river turtles (*Podocnemis expansa*) , yellow-spotted giant river turtles (*P. unifilis*), and, although not of Amazonian origin, rhinoceros iguanas (*Cyclura cornuta*).

The number of species of both fishes and reptiles grew rapidly, and also time and money were invested to improve exhibitry, husbandry, and reproduction. In 1984 I was appointed curator for fishes and reptiles, the first curator for just lower vertebrates and invertebrates at the Zoo[4]. Assink, who had become general curator in 1984, left the zoo six years later.

In the period from the late 1970s until the late 1990s, several "difficult" species were being bred: Amboina sail-tailed lizard (*Hydrosaurus amboinensis*; Visser 1984; Belterman and Visser 1996 [on the chromosomes of *Hydrosaurus*]), white-throated monitor (*Varanus exanthematicus albigularis*; Visser 1981), yellow monitor (*V. flavescens*; Visser 1985), lace monitor (*V. varius*; Horn et al. 1997), Chinese crocodile lizard (*Shinisaurus crocodilurus*; Visser 1989), and leopard tortoise (*Geochelone pardalis babcocki*; Visser and Zwartepoorte 1989). Other species that were more or

less regularly bred include: spectacled caiman (*Caiman crocodilus*), spider tortoise (*Pyxis arachnoides*; Zwartepoorte 2000), African spurred tortoise (*Geochelone sulcata;* Zwartepoorte, *in press*), Fiji banded iguana (*Brachylophus fasciatus*), rhinoceros iguana (*Cyclura cornuta*), Philippine sailfin lizard (*Hydrosaurus pustulatus*), African spiny-tailed lizard (*Uromastyx acanthinurus*; Zwartepoorte1995), ridge-tailed monitor (*Varanus acanthurus*), and mangrove monitor (*Varanus indicus*). In all, more than a hundred species have reproduced in the Rivièrahal so far.

Monitor lizards have always played an important role in the zoo's reptile collection and even in the second reptile house (1953–1974) large water monitors were among the more important species; for years a trio of Timor monitors (*Varanus timorensis*) also lived there (Visser 1975). Initiated by the breeding successes with these varanids, a close cooperation with Prof. Hans-Georg Horn of Sprockhövel, Germany resulted in two papers in the "International ZooYearbook" (Horn and Visser 1989, 1997) which provided up-to-date overviews of world-wide varanid captive reproduction, a paper on the perentie (*Varanus giganteus*) in the wild (Horn and Visser 1988) and a paper on the basic biological data of monitors (Horn and Visser 1991). A mainly herpetological journey through Australia in 1986 resulted in a series of popular articles published in German and Dutch hobby magazines as well as in the Rotterdam Zoo's bimonthly magazine, then called *Dieren*. A close relationship was established with the late Dennis King of Perth, Australia, a well-known varanid expert. King visited the Rotterdam Zoo on several occasions. For the Second World Congress of Herpetology in Adelaide (1993), I assisted him as a convener for the special Varanid Symposium, which was a followup to the successful First Multidisciplinary Varanid Symposium held in Bonn, Germany, after the First World Congress of Herpetology in Canterbury. A general paper on Rotterdam's monitors appeared in the American hobbyist magazine *The Vivarium* (Visser 1992).

The Masterplan Developments: from 1990

In 1988, after Van Dam had retired and Ton Dorresteyn had become the new director, a complete renovation of the Zoo was undertaken and the first draft of the Masterplan was completed in 1990. As in any modern zoo, "habitat immersion" was the leading element of the plan. According to this philosophy, animals should be housed in naturalistic enclosures that resemble natural habitats accessible to visitors (whenever possible). At the Rotterdam Zoo, these habitats or "biotopes" were to be organized on a geographical basis. In 1991 an Asian swamp and large bat cave were completed, and this cave was the first mixed habitat where reptiles were (and still are) housed: in this case, bat-eating ratsnakes (*Elaphe taeniura*). In the "Taman Indah," a tropical Asian jungle house, the Asian elephants and rhinoceroses share their indoor riverine forest habitat with gibbons, hornbills, Asian freshwater fishes, and Burmese pythons (*Python molurus bivittatus*). In an Asian Batak-style house, tokay geckos (*Gekko gecko*) are exhibited in a glass fronted cupboard; in fact this house is also the indoor facility for Asian deer, antelope, and leaf monkeys. After having success with taxa which would thrive in these mixed species exhibits, it was decided that not only mammals, birds, and plants, but always also reptiles, fishes, and insects would be combined in all new habitats, departing from the former idea of a building housing only reptiles (or indeed fishes).

The Oceanium: From 2001

The largest Masterplan project to date opened officially in July 2001: the Oceanium. The visitor is encouraged to take a journey of discovery along coasts and through oceans, starting in Europe, via the Atlantic Ocean to the Americas. As this was planned to be our major indoor exhibit featuring the American continent, it was decided that all of our American herp species should be housed in the Oceanium. Because of the uniqueness of the Caribbean island herpetofauna and our political connection with the Netherlands Antilles, focusing on Caribbean Island fauna was a logical choice. The link with the Caribbean Sea (essential in an Oceanium building!) and its coral reefs is apparent to our visitor: after having viewed the lively reef with schools of fishes and live corals, our explorer slowly rises above the surface of the water to see a surf action aquarium and a tidal mangrove forest. After this watery experience, our traveller reaches an Antillean shore, where the rhinoceros iguana (*Cyclura cornuta*), Roatan Island black iguana (*Ctenosaura oedorhina*), Aruba Island rattlesnake (*Crotalus unicolor*), Cuban boa (*Epicrates angulifer*), Cuban anole (*Anolis equestris*), and Montserrat mountain chicken frog (*Leptodactylus fallax*) are exhibited. Gradually, we plan to substitute the more common species in this Caribbean section with endangered species. The threatened leptodactylid frog *L. fallax*, successfully hatched and raised by the Durrell Wildlife Conservation Trust as part of a safety net recovery plan, is an example of this strategy. In the transition between the "Caribbean" and the "Falkland Islands" king penguin habitat, there is a small but nice South American jungle habitat and one of the tropical river exhibits holds Colombian slider turtles (*Trachemys scripta callirostris*) and dwarf caimans (*Paleosuchus palpebrosus*).

Sonoran Desert species from North America and Mexico were traditionally represented in our reptile collection and North American succulent plants were important in our botanical collection; therefore the Sonoran Desert was chosen to be represented in the Oceanium, and to link this exhibit to the sea, this habitat is called "Sea of Cortez" because well known proximal reptile species are shown: Gila monster (*Heloderma suspectum*), giant black chuckwalla (*Sauromalus hispidus*), collared lizard (*Crotaphytus collaris*), among others. To enhance further the "desert-and-the-sea" image, an open 25,000-liter aquarium contains Sea of Cortez fishes. Burrowing owls, roadrunners, rock squirrels, and Saguaro cactus complete this Sonoran community.

Currently, a very large exhibit is being added to the Oceanium's journey of discovery: The Galapagos Islands. The only live animals to be displayed are ten Galapagos tortoises (*Geochelone nigra*). These chelonians hatched at the Zürich Zoo in 1995 (see Fürrer 2002, for details). The 110 m^2 indoor exhibit and the 160 m^2 outdoor habitat are planned for completion by the summer of 2002. A life-size model of a marine iguana (*Amblyrhynchus cristatus*) will be added as living specimens are protected by Ecuador and not available. The model will also be used as an opportunity for the blind (and others!) to feel some of the essence of a large iguanid lizard.

A Glimpse of the Future: the Renovated Rivièrahal

A donation by the City of Rotterdam will allow us to renovate the Rivièrahal in 2003 and to restore it according to the style created by the architect Van Ravesteijn years ago. The central part of

the hall will feature public amenities with a large indoor sitting area and cafe, and only a few, but sophisticated aqua-terrariums while both wings will be reserved for animal exhibits. The east wing (currently tropical birdhouse) will be connected with the Asian continent and Chinese garden and pavilions, and contain mainly Chinese and Indochinese birds as well as an indoor and outdoor facility for our Chinese alligators (*Alligator sinensis*). Already the former Amazonian wing, adjacent to this tropical birdhouse, was transformed into an exclusively Asian reptile facility for Komodo dragons, brown jungle tortoises (*Manouria emys*), and several freshwater turtle species in June 2002 (Visser 2002). Graphics and videos help to explain the Asian turtle crisis (see Buley and Zwartepoorte 2002) to the public.

The west wing, now housing gorillas and giraffes, will be connected to the African savannah in the near future and will be the place where a selection of African reptiles (including the two old African slender-snouted crocodiles) will be housed. The very popular incubation and neonate displays will certainly hold their important central place in the Hall.

It is the goal of the Herpetological Department of the Rotterdam Zoo to be more involved in international herpetological conservation efforts, and, more specifically, in much needed *in situ* conservation programs. Carefully selected groups of reptiles and amphibians in a unique series of habitats will tell that story to the public and hopefully arouse interest and support from the visitors at the Rotterdam Zoo.

Acknowledgments.—Fred Rueb, head keeper of birds at the Rotterdam Zoo, loaned materials from his famous private archives; Fernande Hazewinkel, volunteer at the Zoo, prepared excerpts from the very old minutes in the Rotterdam Municipal Archives and assisted in many other ways; and Lex Noordermeer, of the Zoo's Communication and Marketing Department, and the one in the zoo with the greatest awareness of the history of the Zoo, checked the text to keep me from making horrible mistakes. Thanks!

Footnotes:

[1] Most of the pre-war records of the Zoo were destroyed in a fire during the war, except for the books that contain the records of animal gifts, births and sales. These happened to be in a metal vault. The book of animals obtained by purchase is no longer available, so it is not possible to determine which reptile species were mostly sought after by the zoo's pre-war management and thus to reconstruct some sort of "collection plan."

[2] The Reptile House would eventually return to its original function as a thematic Indonesian/Chinese restaurant in the Asian part of the zoo.

[3] The pair of alligators died in the nineties of the last century, Bobby the male, in 1991; in 1966, Judith the female was shown post mortem to have been a male as well....Both *Crocodylus cataphractus* survive until today.

[4] Traditionally, and in contrast with the North American Zoos, many of the older and larger European zoos appoint curators for both reptiles and fishes, and of course very often their duties include overseeing amphibians and invertebrates. Examples are: Amsterdam, Rotterdam, Antwerp, Berlin, London, Leipzig, Frankfurt, Stuttgart, and Cologne. Inevitably, curators will be biased toward a specific group of animals. This is often noticeable in the quality of research, collection and exhibition.

Timing of Reproductive Immigration in Salamanders: Roles of Environmental Cues and Endogenous Biological Clocks

MICHAEL S. GRACE
Department of Biological Sciences, Florida Institute of Technology
150 West University Boulevard, Melbourne, Florida 32901, USA
e-mail: mgrace@fit.edu

As a behavioral neuroscientist specializing in sensory systems and the neural bases of circadian rhythmicity, I was intrigued to discover spotted salamanders (*Ambystoma maculatum*) in central Virginia migrating to ephemeral ponds much earlier in 1998 than I had expected. Although it is possible that they were migrating in direct response to the wet weather and unseasonably warm temperatures at the time, it is also possible that their migration was influenced by internal time-keeping mechanisms endogenous to the salamanders. If so, how important are environmental cues, how important are endogenous clocks, and how might the two interact? Most literature accounts stress the importance of abiotic environmental factors in mediating the timing of migration and reproduction in salamanders, though some authors have suggested that endogenous clocks might influence the timing of seasonal reproductive activities. Even so, most discussions of endogenous cues affecting the timing of migratory behavior and reproduction have been cursory, and in some cases have suffered from a lack of depth in understanding the roles and mechanisms of the endogenous oscillators involved.

My goal here is to describe some of the various possible (and likely interacting) mechanisms that control the timing of seasonal migration in salamanders. Future experimental and observational work will be much improved by better understanding and careful discussion of the problems and possibilities generated by a suite of sensory systems and endogenous oscillators that allow exogenous (abiotic) and endogenous factors to interactively modulate the precise timing of reproductive activities within a given season.

En masse breeding migration occurs in many salamander species (see, for example, Gill 1978; Palis 1997; Petranka 1984; Semlitsch 1981; Shoop 1960; Spotila and Beumer 1970; Twitty 1959; Twitty et al. 1964); this behavior might have evolved as an anti-predator mechanism. Large numbers of migrating individuals might saturate the predator pool at a given moment in time, effectively allowing more individuals to successfully reach breeding sites (such as ephemeral ponds) than would do so if migration were asynchronous. Alternately (or in addition), *en masse* migration might increase the likelihood of males and females encountering each other at breeding sites, and might affect competition between individuals for mates.

Regardless of the selective advantage of mass migratory behavior, there is still much to learn about the mechanisms underlying migratory synchrony in salamanders. One complication in understanding these mechanisms is that the timing of synchronous migration and/or breeding varies among species, sometimes greatly. For example, in the eastern United States, *A. maculatum* immigrates to breeding sites and breeds in late winter to early spring (Baldauf 1952; Blanchard 1930; Hillis 1977), whereas *A. opacum* breeds in autumn (Anderson and Williamson 1973; Graham 1971). Although the timing of immigration/breeding is grossly similar from year to year (i.e., spring, autumn…) within species, the exact timing of a species' immigration/breeding can vary significantly (see Semlitsch 1993). That is, while the seasonality of reproductive activities is fixed in a given species, the timing of its migration and reproduction exhibits remarkable plasticity within that season for a given species.

The findings of Blanchard (1930), Hillis (1977) and others suggest that the interacting influences of temperature and rainfall are important effectors of immigration in *A. maculatum*. Blanchard (1930), for example, concluded that vernal immigration is initiated by the first rains following snowmelt and ground surface thaw. Beneski et al. (1986) stated flatly that once permissive temperatures occur, migratory activity in ambystomatid salamanders depends upon the occurrence and/or amount of rainfall. Sexton et al. (1990) concluded that three-day average temperature (mean of daily high and low temperatures) is the most useful predictor of *A. maculatum* immigration, but noted that all immigration in their study was associated with rainfall.

Environmental factors alone cannot fully explain the timing of reproductive activity within a season, however. While factors such as rainfall and temperature certainly serve as cues for breeding activity, and variability in timing of migration/breeding can be influenced by variability in these cues, breeding activities might also be affected by endogenous circannual and circadian clocks. Sexton et al. (1990) hypothesized that the lack of immigration of *A. maculatum* during December and January despite favorable conditions of temperature and rainfall represented a refractory period perhaps based upon an endogenous circannual clock. However, this is a rare example in which internal clock control has been discussed as a mediator of seasonal reproductive behavior in salamanders.

We (Grace and Church 2003) observed *A. maculatum* migrating in early January and early February in Albemarle County, Virginia. Our observations of migration on warm rainy nights support previous general conclusions that increased temperature and nocturnal rainfall influence immigration of ambystomatid salamanders to vernal breeding ponds (Douglas 1979; Hillis 1977; Sexton et al. 1990). Our observations also agree with previous reports that male *A. maculatum* immigrate before females (Douglas 1979; Grace and Church 2003; Hillis 1977), and with Sexton et al.'s (1990) model of immigration induction by a minimum three-day average temperature of approximately 5.5°C in conjunction with 0.127 cm minimum rainfall the day of immigration (Grace and Church 2003). However, the migratory activity we observed occurred significantly earlier than reported in even more southern portions of the species' range (e.g., North Carolina: Brimley 1921; Gray 1941; Harris 1980; Tennessee: King 1939), and corresponded with the earliest reported migration times for the southernmost portion of the range. Mount (1975), for example, documented migrations from late December to early February in Alabama; Walls and Altig (1986) reported late December and early January

migrations in Mississippi.

Though our observations are at odds with Sexton et al.'s (1990) hypothesis that a clock-derived refractory period prevents immigration during December/January (in St. Louis Co., Missouri), they do not negate the possibility that clocks are involved in regulating the timing of reproductive activities. Rather, our observations, together with those of others, suggest that clocks might influence seasonal activities in complicated ways, and that clocks interact with exogenous, abiotic cues in the temporal control of seasonal reproduction.

Locomotor activity in salamanders is affected by internal clocks, and clock-controlled behavior responds to environmental cues (Maerz et al. 2001). Thus, the effects of endogenous clocks on physiology and behavior are not fixed. If a circannual clock produces a refractory period for *A. maculatum* immigration, then the difference in immigratory behavior between salamander populations of the same species (cf. Grace and Church 2003; Sexton et al. 1990) might be due to significant plasticity in clock output, or to differences in the timing of cues that entrain the circannual clock to environmental time. Alternately, the timing of expression of seasonal activities in salamanders might be determined by interaction between circadian clocks and environmental cues.

Photoperiodic time measurement is accomplished through photoperiodic photosensitivity—circadian clocks are differentially sensitive to light according to time of day such that at certain times of year (but not others) light occurs during photosensitive times of the circadian day. Photoperiodic time measurement is a phylogenetically widespread mechanism underlying the timing of seasonal reproduction in vertebrate and other animals (for review, see Gwinner 1981). It could be argued that photic input to endogenous clocks is of little importance in fossorial organisms such as ambystomatid salamanders. Little is known about circadian organization in salamanders, but note that even in a fossorial mammal that completely lacks visual photoreceptors (the blind mole rat *Spalax ehrinbergi*; Cooper et al. 1993), photic input to the circadian timing center is fully developed (David-Gray et al. 1998).

If photoperiodic entrainment of endogenous clocks is involved in seasonal migration, then populations of *A. maculatum* in Missouri and Virginia might have evolved differences in clock-controlled timing of immigration (because seasonal variations in daylength are similar in Virginia and Missouri: for 5–7 January 1996, photophase in Charlottesville was approximately 9 h 38 min, and in St. Louis 9 h 35 min; for 9–11 February 1996, photophase in Charlottesville was approximately 10 h 39 min, and in St. Louis 10 h 35 min). Alternately (and more likely) the immigratory refractory period might be sufficiently plastic to respond to significant annual variation in temperature and rainfall. Finally, temperature and rainfall might be both proximate cues mediating initiation of immigration and seasonal cues mediating entrainment of endogenous circannual clocks in *A. maculatum* (Fig. 1).

It should be noted that Anderson and Williamson (1973) argued against the involvement of photoperiodic time measurement in the control of *Ambystoma opacum* reproduction. They concluded that nesting in *A. opacum* is temperature dependent (Anderson and Williamson 1973), occurring as temperatures drop below some threshold such that northern populations breed prior to southern ones. However, photoperiodic time measurement in vertebrate animals can be very sensitive, and *A. opacum* might be able to distinguish between northern and southern photoperiods on any

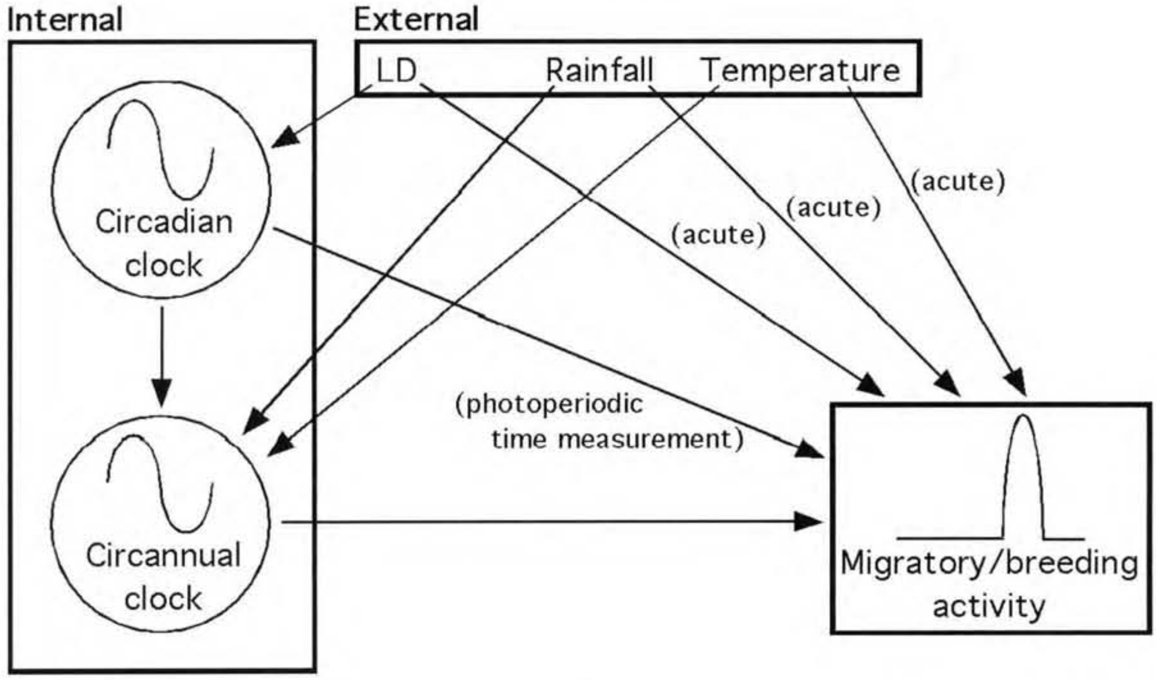

FIG. 1. Model of exogenous cues and endogenous clocks influencing the timing and plasticity of timing of seasonal immigration and reproduction in ambystomatid salamanders. Circadian and/or circannual clocks might mediate seasonal activities, perhaps through photoperiodic time measurement. Light (LD = light/dark cycle), temperature and rainfall might act either as direct acute cues affecting behavior, or entraining cues for clocks, In addition, changing daylength according to time of year might serve as a photperiodic signal for seasonal reproduction. Any or all of these cues and mechanisms might interact in the temporal control of overt behavior.

given day. Therefore, *A. opacum* might exhibit a photoperiodic response threshold, while temperature and/or rainfall might serve as acute permissive or stimulatory factors for reproduction.

Several authors have noted that in vernal immigrations of ambystomatid salamanders, arrival of males precedes arrival of females at breeding sites (see Beneski et al. 1986; Petranka 1984; Semlitsch et al. 1985). Some have suggested that males and females differ in threshold of response to acute cues (rainfall and/or temperature) for migratory activity (Douglas 1979). This might be the case, but circadian and/or circannual clocks might also underlie differential timing of male/female arrival at breeding sites. That is, males and females might differ in the timing of migratory activity relative to internal clock time (the "phase angle" of migratory activity). It is well known that phase angles of responsiveness to environmental cues differ among species, but there has been little exploration of sex-specific differences in phase angle, and none (to my knowledge) related to amphibian clock-controlled behavior. There is precedent, however: Helfrich-Forster (2000) described sex-specific differences in phase angle of daily locomotor activity in *Drosophila melanogaster*. It is reasonable to suspect that if circadian and/or circannual clocks are involved in the control of salamander breeding activities, sex-specific differences in phase angle of seasonal breeding behavior might have arisen as an adaptation promoting male arrival at breeding sites prior to female arrival.

In summary, multiple factors probably control salamander reproductive migration and breeding, and these factors likely include both internal and external components (Fig. 1). The fact that the timing of reproductive activities within a season exhibits remarkable plasticity even though reproductive efforts in a given species are confined to a season, suggests that salamanders consult both external sensors and internal clocks in the control of the timing of reproductive activities. Rainfall, temperature, and the daily light-dark cycle might act as proximate cues mediating acute changes in reproductive activity: ambystomatid salamanders tend to immigrate to breeding ponds at night in rain and at temperatures above some threshold. Each of these factors might also affect endogenous oscillators (circadian and/or circannual) that drive seasonal changes in reproductive physiology and behavior. The daily light-dark cycle likely entrains a circadian oscillator(s), and seasonal changes in daylength, measured by acute effects on the circadian oscillator, might be used as cues for the seasonality of reproductive activity. Rainfall and temperature might then act as permissive cues against a background of internal clock control, which is in turn sufficiently plastic to allow response to acute proximate cues within a window of seasonal opportunity.

Clocks are hot. The cellular and molecular mechanisms of clockworks themselves have been studied extensively in recent years, as have been neural, cellular, and biochemical mechanisms through which environmental cues affect internal oscillators (see almost any recent issue of *Science* or *Nature*). Many clock investigators are now returning to the previously popular study of clock-controlled outputs, including clock-controlled timing of overt behavior; these studies are largely based in the laboratory. However, despite the great number of past laboratory investigations of clock function, little is known about how clocks affect the behavior and physiology of animals in their natural environments (but see DeCoursey et al. 1997, 2000, for excellent studies of clock function in wild rodents living in natural habitats). Highly synchronous mass reproductive events in salamanders provide important opportunities to investigate the interacting roles of internal clocks and acute environmental cues in the control of seasonal and daily timing of complex behavior in amphibians. Furthermore, such studies in salamanders might serve as important models for understanding the regulation of timed behavior in vertebrate animals generally.

Yale University, New Haven, Connecticut 06520-8106, USA
e-mail: theodora.pinou@yale.edu

Xenodermatid snakes (Dowling 1988), often referred to as "Xenoderminae" or "Xenodermatinae" subfamilies of the century-old, polyphyletic "Colubridae" of Boulenger (1893–1896) [which is equivalent to the current taxon Caenophidia, minus the Viperidae] comprise an ancient clade of moisture-loving caenophidian snakes distantly related to *Acrochordus* and homalopsids (e.g., a member of the Acrochordoidea). Xenodermatid snakes are currently considered to be an Oriental taxon made up of four (Smith 1943:123; Underwood 1967:80–86) to six (McDowell 1987:35; Zaher 1999) genera. Bogert's (1964) summary of "xenodermine-like" characters seemed to confirm that "xenodermines" were an Oriental group with a few genera that were unrelated to other snakes (including those in South America) that possessed some elements of similar morphology.

Thus, most recent studies of American snakes have excluded any consideration of the Xenodermatidae. Instead, the unrecognized xenodermatid genera have been placed in the "Xenodontinae" (Hillis 1990; Myers 1986) or "Dipsadinae incertae sedis" (Zaher 1999), or merely in the Tribe Nothopsini without familial designation other than "colubrid" (Sheil and Grant 2001).

A clarification of the relationships of these snakes seems overdue. We are now engaged in a world-wide review of xenodermatid snakes (Dowling and Pinou, MS) and have discovered eight morphological characters (three of which [1, 2, 7] are unique) that serve to identify clearly the members of this family. To clarify the distinctive nature of this family and to avoid further phylogenetic and taxonomic confusion, we present a brief summary of these characters herewith.

Distinctive Morphological Characters of Xenodermatids

Our recent assessment of newly recognized distinctly xenodermatid morphological characters demonstrates that this ancient family is much larger than is currently acknowledged, comprising more than 20 genera that are distributed from Japan, China, and India to Australia, Africa, and South America (Table 1). We provide a list of the major distinguishing features of the family here because many have been commonly omitted from both past and current taxonomic descriptions—or are erroneously described.

A key morphological feature of xenodermatids is 1) the forward-facing position of the expanded and projecting nostrils, which has been rarely noted in descriptions (although often shown in figures; *v.* Fig. 1) since Boulenger's (1893:175) notice of it. [An excellent photograph showing the expanded nostril in *Nothopsis* is Fig. 3a in Köhler and Schmidt 2001.] Correlated with this, 2) the nasal scute (often described as paired, but see Sheil 1998) is depressed into the supralabial row, often reducing the height of the first supralabial scute so as to make it almost invisible (Pope 1935:182).

Another key feature is the 3) presence of juxtaposed (rather than imbricate) dorsal scales in at least the five middorsal rows. This often leaves extensive areas of bare skin between rows, making the small members of this family highly susceptible to desiccation. Pope (1929; repeated in 1935:186) stated of the xenodermatid *Achalinus:* "It is extremely delicate and dies more readily than almost any other snake. Soon after death it dries and hardens in a most unusual way." A specimen of *Synophis* from Ecuador (USNM 233063) examined by HGD shows this condition.

Another distinctive feature is 4) the shape of the pupil of the eye—which has been misreported in almost every description. Living xenodermatids have eyes with vertically elliptic pupils, thus providing a clearly visible distinction in living individuals from the round pupils of natricids, with which they are commonly confused. It is unfortunate that workers who describe pupil shapes from preserved specimens have not read (or not heeded) Walls's (1932) warning of long ago:

> "It is obvious that the form of the pupil should be accurately noted in descriptions. Contradictory statements abound, most of which could have been avoided if all mention of pupil shape had been omitted when no living material of the species was available to the describer. It does not seem to be fully appreciated that a vertical pupil becomes round in dim light; nocturnal reptiles caught and killed at night when their pupils are dilated, will often exhibit round pupils in the preserved condition. Even when pre-

served in the light, a vertical pupil sometimes distorts artificially into a round form."

Another feature, apparently noted only by Cope (1871) and Underwood (1967:80–86), is 5) the shape of the postorbital bone in xenodermatids. Underwood reported it as "T-shaped" but we believe that "inverted L-shaped" is a more accurate description. The anterior dorsal element of the postorbital bone extends to a variable degree over the orbit, as in *Acrochordus* and homalopsids.

Most of the descriptions of xenodermatids have emphasized the 6) presence of posterior hypapophyses in this family. We find that the "hypapophyses" in xenodermatids are not the distinctive, recurved processes of natricids nor the narrow, straight elements of viperids and some colubrids *(s.s.)*, but vary widely, typically occurring as a slightly expanded, narrow subcentral ridge in small snakes such as *Achalinus*, but are expanded into a large compressed keel in large snakes such as *Mehelya.*

Expansion and ornamentation of the neural spine and the pre-and/or post-zygapophyses have been used as distinguishing features of xenodermatids, but these are found in only a few xenodermatid genera and those outside the Oriental region were dismissed as convergent by Bogert (1964). The 7) expansion and overlapping of the zygapophyses to form lateral ridges on the body and the posterior hypapophyses seem to be the only consistent features of vertebral morphology for members of this family (*v.* Fritts and Smith 1969; Sheil 1998; Sheil and Grant 2001).

As suggested by the name (*xeno-*, strange; *dermis*, skin), most of the snakes in this family have some unusual elements of head scutellation. Although many xenodermatids have the nine dorsal head scutes typical of caenophidians, this number is often reduced through fusion or loss. Also, scales similar to the dorsal body scales might invade the spaces between the scutes (e.g., *Stolizkaia: v.* Rooij 1917:46*)* and in extreme cases (e.g., *Xenodermus: v.* Rooij 1917:45*)* only the internasal (or perhaps, prefrontal) scutes remain. Similarly, loreal, ocular, and/or temporal scutes of the head might be absent through fusion with adjacent scutes (Fig. 1). In some xenodermatids the labials have everted edges, and the ventral scutes of the head region might also be modified to form unusual patterns (*v.* Smith 1943:129).

The 8) morphology of the hemipenis might possess distinctive features but, like the pupil of the eye, is often misrepresented in taxonomic descriptions because of poor specimen preparation, thus casting some doubt on the degree of similarity among genera. As stated by Smith (1943:128) for *Achalinus,* the proximal region is short (ca. 4 subcaudals in length), but a pair of very slender lobes extends to subcaudal (SC) 24. The sulcus is forked and centrifugal and extends to the tips of the lobes. As described in this and other taxa, the ornamentation usually consists of spines near the fork, with the lobes variably ornamented with spines, papillae, flounces, and calyces—thus, quite unlike natricids, which have a purely spinose hemipenis with a centripetal sulcus, or dipsadids, which have capitate hemipenes (Pinou and Dowling 1994). Some of the Ethiopian genera show the *Achalinus* hemipenial pattern (*Mehelya*, AMNH 12053, paired lobes 21 SC; *Pseudaspis*, Fig. 63 in Broadly 1983). Whether the elongate lobes are characteristic of all members of the family is unknown; they are generally incompletely everted in preparations, with the extremely thin lobes mistaken for retractor muscles. The only other taxon showing this pattern to our knowledge is the King Cobra, *Ophiophagus hannah* (HGD-HISS 76152, paired lobes, 55 SC). As shown by the misshapen hemipenial bodies and vast differences shown between species of the same genus, we are confident (*v.* Dowling 2002a) that Zaher's (1999) illustrations of the American xenodermatids *Nothopsis* (Fig. 88, upper; *Synophis* (Figs. 88, lower; 89, upper) and *Xenopholis* (Fig. 95) are photographs of incompletely-everted organs.

The only molecular data on xenodermatids are contained in Cadle's (1994) immunological survey of African snakes, in which he compares antiserum from *Mehelya* with serum of 25 African "colubrids," which include 16 of Bogert's (1940) 18 recognized "Groups." [The two groups missing are both Colubridae *(s.s.)*, but he included a total of seven colubrids *(s.s.)*.] In addition, he included *Leioheterodon* from Madagascar. He found none closer than 70 immunological distances (AID). The usual conversion (1.7 AID = 1 million years) suggests a minimum divergence time of 41 million years ago (mya) (= Upper Eocene).

American Xenodermatids

The recognition of xenodermatids in Tropical America has been delayed because of past emphasis on features of vertebral morphology and head scutellation in current taxonomic descriptions, and the neglect of those eight features (listed above) that are diagnostic. Bogert's (1964) highly restrictive review of American xenodermatids, and his discussion in that paper of the vertebral morphology of the dipsadid, *Ninia,* have contributed to this lack of recognition. By using the characters noted above, we recognize five Central and South American genera as members of the Xenodermatidae. These are *Diaphorolepis* (Jan 1863), *Emmochliophis* (Fritts and Smith 1969), *Nothopsis* (Cope 1871), *Synophis* (Peracca 1896), and *Xenopholis (*Peters 1869*)*.

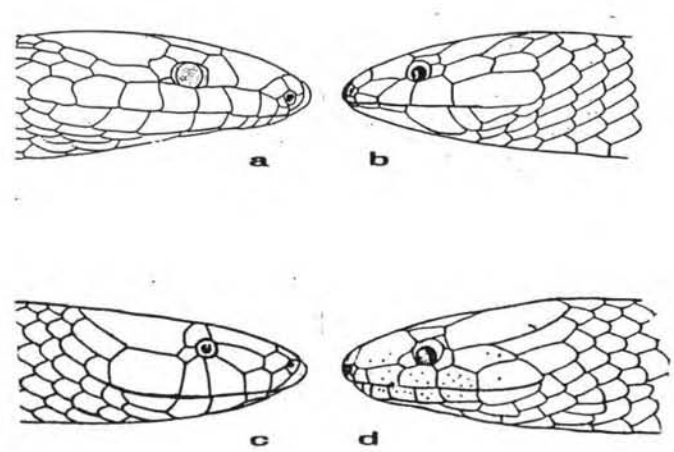

FIG. 1. Lateral views of the head scutellation in four similar genera of xenodermatid snakes. (a) *Emmochliophis fugleri*; (Ecuador); (b) *Xylophis perroteti* (India); (c) *Agrophis sarasinorum* (Celebes); (d) *Aspidura trachyprocta (Ceylon)*. Note the frontal position of the nostrils correlated with the reduction in height of the first supralabial. Note also the various reductions or absences of the loreal, ocular, and temporal scutes. The round pupils of the eyes are drawn from observations of preserved specimens; the pupils of living xenodermatids are vertically elliptic. [Figures are from: (a) Fritts and Smith 1969; (b) Smith 1943; (c) de Rooij 1917; (d) Smith 1943.]

The status of *Nothopsis* as a xenodermatid has been in doubt (e.g., Underwood 1967:85–86). Recently, however, one of us (HGD) had the opportunity to examine four specimens of this genus, including the type specimen of *N. torresi* Taylor (1951) [= *N. rugosus* Cope, *f.* Dunn and Dowling 1957], at the University of Kansas Museum of Natural History. All have the expanded and forward-facing nostrils and juxtaposed dorsal scales along the upper portion of the body that are typical of xenodermatids. Unfortunately, the type specimen, which is a male (KU 25719), is the only adult (BL 278; TL 117). The other three are very small (BL 128–145) so no skulls can be prepared from the KU specimens.

Several genera *(Ninia, Chersodromus,* and *Tretanorhinus)* that have posterior hypapophyses are found in lower Central America, thus overlapping the geographic range and possessing one of the vertebral characters of the xenodermatid snakes (expanded neural spines), as well as having some features of scutellation and color that are similar. However, they are clearly dipsadids on the basis of their short, capitate hemipenes (Pinou and Dowling 1994; pers. observ.) and their immunological similarity to *Dipsas* and other dipsadid genera (Cadle 1984). Bogert (1964) also investigated *Ninia* as a possible xenodermatid, but ultimately decided that neither it nor any other American snake belonged to that taxon.

The reviews by Dunn and Dowling (1957) and by Bogert (1964) utilized only the morphological characters recognized at that time, and the hemipenis drawing of *Nothopsis* (Plate I in the former paper) is uninformative except to show that there are basal spines and the sulcus is forked. The description of the postorbital bone of the skull provided by C. M. Bogert in both papers is so different from that described by Cope (1871), who found elements extending across the orbit, that it brings into question the completeness of the skull examined by Bogert. We encourage workers at institutions with specimens of *Nothopsis* available to investigate this important morphological element, as well as the other distinctive features of xenodermatids.

Because of the incomplete surface coverage of juxtaposed dorsal scales, all xenodermatids need moist conditions for life. Most of the genera are semifossorial dwellers of moist rainforest or cloud forest regions. As might be expected of an ancient group, however, they vary from arboreal *(Stoliczkia)* to surface-terrestrial *(Mehelya)* and stream-dwellers *(Achalinus),* and range in elevation from near sea level to more than 1500 m. Several of both the Asian and the American species have been found in high elevation cloud forests. Most of the small species feed on earthworms, but salamanders, frogs, and lizards are preyed on by some. A few of the larger Old World species have been found to feed on other snakes.

Presumably, the American representatives of this family came into North America from Asia over the Bering Strait during the Middle to Late Miocene 16–10 mya (Dowling 2002b; Holman 2000), during a period when the sea level was low and temperatures were high (McKenna 1983). Like other tropically adapted species, they were forced southward into Central America by the cooling climate of the Pliocene where they remained, along with many similarly-adapted crotalids, elapids, and colubrids. Thus, they did not enter South America until the closure of the Panama gap in the Pliocene (ca. 3 mya).

The restricted habitats and nocturnal habits of xenodermatids have made them a little known group in the Americas. Few species have been described from more than two individuals, and most of the descriptions are incomplete or give erroneous information. The list of characters given above might aid in the recognition of additional taxa in this region. The species that inhabit the highly threatened cloud forests deserve special attention.

Acknowledgments.—We thank Kraig Adler, William Duellman, and John Simmons for their aid in making possible HGD's examination of the specimens of *Nothopsis* at the University of Kansas Museum of Natural History. We also thank the 3–5 unknown reviewers who commented at length on the manuscript and, no doubt, vastly improved its clarity. Finally, we thank the two editors involved, Gunther Köhler and Robert Hansen, who went out of their way to process our manuscript in spite of numerous divergent opinions in assessment.

A Survey of New York State Pet Stores to Investigate Trade in Native Herpetofauna

SUZANNE M. HOHN*
Biodiversity, Conservation and Policy Program, Biology Department
University at Albany, State University of New York
Albany, New York 12208, USA

**Present address: Majete Wildlife Reserve*
P.O. Box 25, Chikwawa, Malawi
e-mail: smh116@hotmail.com

Although numerous factors have been implicated as contributing to global herpetological declines (e.g., habitat loss or degradation [Cooke 1972; Lannoo et al. 1994], pollution [Beebee et al. 1990], ultraviolet radiation [Blaustein et al. 1994]), commercial exploitation is gaining recognition as an issue for many species (Galligan and Dunson 1979; Jennings and Hayes 1985). Collection of animals for the pet trade is suspected to have contributed to some population declines (e.g., McCollough 1997) although few studies provide direct evidence of this (but see Klemens and Moll 1995; Macmillan 1987).

In New York State, 29 of 75 endemic species of amphibians and reptiles have state or federal status of concern (i.e., classified as endangered, threatened, special concern, or protected game; Title 6 of the New York Code of Rules and Regulations, Part 182). Factors believed to have contributed to declines in New York herpetofauna include habitat loss and degradation, unregulated collection, and illegal collection (Breisch 1997). Little is known about the relationship between the pet trade in New York and wild herpetofaunal populations. Of the 29 species of concern, 14 have endangered or threatened status and two are protected game species; these 16 species cannot be collected or possessed at any time without a scientific collection license (Levell 1997). Thus, collection is legally restricted for over half of the concern species, an action that should remove these taxa from the New York State pet trade. The remaining 13 species of special concern can be collected or sold without limit.

To investigate the relationship between the pet trade and wild populations of amphibians and reptiles in New York, I conducted a survey of pet stores and their suppliers. The primary objectives were to determine if native New York species, especially concern species, are sold in stores and if the animals are collected from the wild to supply the New York pet trade. My survey consisted of informal interviews with employees of pet store and their suppliers, from which I expected to collect general information to approximate the extent and potential impact of trade.

In April 1998, I obtained a list of 711 pet stores in New York State from GTE Superpages (http://yp4.gte.net). I used a random number table to select 100 stores, and then contacted each store to ask whether they sold amphibians or reptiles. Employees at 45 stores responded that they sold these animals; employees at 34 stores said they did not. Telephones were not answered or had been disconnected at the remaining 21 stores.

In June and July 1998, I visited 44 of the pet stores that reportedly sold amphibians and reptiles (I was unable to visit the 45th store because of its location). At each pet store, I showed an employee a list of 74 herpetofaunal species found in New York. I asked: if the store sold any of those animals; how many individuals per species were sold per year; what was the price per individual per species; and from where the animals came. I inspected each store for animals from my list and for signs advertising those animals for sale.

Animal supply companies were indicated as sources for many species. In March 1999, I attempted to contact 10 suppliers indicated as sources by seven pet stores. I was unable to find a phone number or address for three suppliers, but I was able to contact the remaining seven supply companies. I asked each supply company about the species sold in pet stores using that supplier; in a few cases, I asked the supplier about additional animals. In total, I asked suppliers about 24 species, eight of which were concern species. I asked each supplier: if they sold those species; whether the animals were captive-bred or wild-caught; and, if wild-caught, from where the animals came.

Employees at 37 stores responded to my survey and indicated animals they sold. At five stores, I received no help but observed animals on my list, or saw signs advertising those animals for sale. Of 74 amphibian and reptiles species found in New York, 45 (61%) were reported as sold in at least one pet store (Table 1). Pet stores sold 15 of 29 (52%) concern species. This included 4 of 16 (25%) protected species, which require a license for possession: tiger salamander (*Ambystoma tigrinum*), eastern box turtle (*Terrapene carolina carolina*), mud turtle (*Kinosternon subrubrum subrubrum*), and wood turtle (*Clemmys insculpta*). The tiger salamanders, eastern box turtles, and mud turtles sold might have represented species or subspecies not found in the wild in New York; however, it is illegal in New York to sell any subspecies of the tiger salamander and any North American box turtle.

The reported number of individuals sold per species per store per year ranged from 1 to 1000 (mean = 60, SD = 136). With one exception, the average number of individuals of concern species sold per store was low (an average of less than five individuals

TABLE 1. New York State amphibian and reptile species sold in New York pet stores. — indicates that pet stores or suppliers did not provide that information.

Species	Status	Stores selling/ stores sampled	Average no. sold per year	Average price	Suppliers selling/ suppliers sampled

[1] (No. stores providing information, standard deviation)
[2] this is a new status, which the species did not have at the time of the survey
[3] the store sample size is raised when I saw the animal, yet the store did not report selling it

sold per year per store was reported for five species and an average of between 7 and 12 individuals was reported for eight species; Table 1). The exception was the southern leopard frog (*Rana sphenocephala utricularia*), for which one store reported selling 500 individuals per year. The store reporting this exception was a store that reported selling animals in much higher numbers than other stores. Whereas the highest number of animals any other store reported selling was 200 individuals of a species per year, this store reported selling 300 individuals for two species, 500 for one species, 600 for three species, and 1000 for one species (red-eared slider, *Trachemys scripta elegans*). Results on the numbers of individual animals sold per year might be skewed because of this store.

Prices (in US$) of animals also varied among stores and taxa (mean = $15, SD = $17; Table 1). Average prices per animal were: salamander, $10 (N = 24 prices provided by nine pet stores for 10 species); frog, $5 (N = 21 prices, 13 stores, eight species); turtle $14 (N = 75 prices, 36 stores, nine species); lizard $11 (N = 4 prices, three stores, three species); and snake, $34 (N = 23 prices, 10 stores, six species). The most expensive salamander (tiger salamander, $24) was an endangered species, while the most expensive frog (eastern spadefoot, *Scaphiopus holbrookii*, $20), turtle (diamondback terrapin, *Malaclemys terrapin terrapin*, $50) and snake (eastern hognose snake, *Heterodon platirhinos*, $83) were species of special concern. The average price for every concern species, except for the spotted salamander (*Ambystoma maculatum*) and the northern fence lizard (*Sceloporus undulates hyacinthinus*) was higher than the average price for non-concern species in the corresponding order (Table 1).

The higher prices for concern species might reflect scarcity, a premium accorded to rare animals, or a premium associated with illegal sales of animals. Given the willingness of most store employees to answer questions and the evident confusion over New York State conservation regulations (in five pet stores, an employee told me it was illegal to sell any native species), the latter seems an unlikely factor.

Of the 23 pet stores whose employees provided information on the source of their animals, 11 used in-state suppliers and 12 used out-of-state suppliers. One store reported having bought animals at reptile expositions. Six stores received some animals from private individuals, including children. Additionally, one store reported that employees collected some animals (spring peepers [*Pseudacris crucifer crucifer*], and northern leopard frogs, [*Rana pipiens*]) from the wild in their area.

Of seven suppliers contacted, I received useful information from five, three of which supply animals to 20–50 pet stores in New York State. Two suppliers were based in New York, two in New Jersey, and one in Florida. In all, suppliers reported selling 12 of the 24 species about which I asked. Two of the 12 were concern species (southern leopard frog and spiny softshell, *Apalone spinifera spinifera*).

Of the 12 species sold by suppliers, five amphibians and four reptiles were described as primarily wild-caught animals (Table 1). Suppliers reported three reptile species and no amphibian species as captive-bred. Red-eared sliders and spiny softshells were described as both wild-caught and captive-bred. Suppliers did not report selling eastern hognose snakes or eastern milk snakes (*Lampropeltis triangulum triangulum*), but said that those species

were primarily captive-bred.

Specific locations given by the suppliers for some of the wild-caught animals were: Arkansas (map turtles and red-eared sliders), Florida (bullfrogs, *Rana catesbeiana*), Louisiana (gray treefrogs, *Hyla versicolor*), and Minnesota (common garter snakes, *Thamnophis sirtalis*). No supplier reported selling animals taken from the wild in New York.

Information on the source of animals can be compared with information from Enge (1992), who discusses the source of amphibians and reptiles sold in Florida in one year in the early 1990s. Florida has greater herpetofaunal diversity than New York, but comparisons might be useful. In all, Enge found that 2 of 16 frog species and none of the 12 salamander or newt species were bred in captivity. This is similar to what suppliers told me—suppliers did not report any of 12 amphibian species as captive-bred. Regarding reptiles, at least one individual from nine turtle species and from nine snake species sold in Florida was captive-bred (out of 13 turtle species and 32 snake species). Similarly, suppliers told me two of three turtle species could be captive-bred, although all three of these species also were reported as wild-caught. Three of five snake species were described as captive-bred. Of the animals from Florida sold into the pet trade in one year, 61% were reported as collected from the wild; of species I discussed with suppliers, 75% were described as primarily collected from the wild. Both Enge's results and mine suggest that many amphibians and reptiles supplied to pet stores are wild-caught, although reptiles are more likely to be captive-bred than amphibians.

The two animals sold in the most stores were red-eared sliders (sold in 39 of 41 stores) and painted turtles (*Chrysemys picta*) (sold in 25 of 38 stores). Of the remaining species, none was sold in more than 12 stores each. Red-eared sliders are not native to New York and many of the painted turtles sold might have been western painted turtles (*C. picta bellii*) rather than the two subspecies native to New York, *Chrysemys p. picta* and *Chrysemys p. marginata* (in two pet stores, I saw signs advertising western painted turtles). This suggests that the demand in the New York pet trade for native species, as measured by sales volume alone, is smaller than that for non-native species.

There are several limitations to these results. The interviews in stores were conducted with store employees, who might or might not have had clear or reliable knowledge of what was sold or in what quantities. Employees might have reported selling animals they did not actually sell. For example, employees often confused firebelly newts (*Cynops* spp.), which are not found in New York, with red-spotted newts (*Notophthalmus viridescens viridescens*). As already noted, in some cases, animals reported as sold in pet stores might have belonged to species or subspecies not found in the wild in New York. Additionally, employees obviously gave estimations—they provided numbers during the interview without looking in records to find exact information. For the number of animals sold per year, people often gave estimates in multiples of 5s or 6s. Information I received from suppliers was anecdotal; they only told me whether animals were mainly captive-bred or wild-caught, without giving me any numbers.

In summary, 4 of 16 protected New York State species were reported as sold in pet stores. At the time of my survey, nine species of special concern could legally be collected or sold in New York, and at least six of those were sold in pet stores. Of 12 species sold by suppliers, nine were described as primarily wild-caught animals. No supplier reported selling animals taken from the wild in New York. However, one store reported selling frogs collected from the wild in New York. Employees from at least five stores relayed incorrect information about regulations for native herpetofaunal species.

These results highlight several possible conservation issues resulting from the New York pet trade. Despite the higher demand for non-native species, the fact that native herpetofaunal species were reported as sold indicates there is a market for those species. Many of the animals sold by suppliers to pet stores came from the wild and at least a small number sold in pet stores came from the wild in New York. If customers buy animals of concern species, an incentive to collect those animals from the wild might develop. For each concern species, the state or federal government has documented a concern or risk regarding that species' viability; collection of wild specimens of those species might increase the risk for that species.

In consideration of these issues, I have three recommendations. Firstly, further investigation into New York's pet trade would provide more complete and quantitative information. While this study has provided general information regarding trends occurring in the New York pet trade, the limitations of the study prevented an accurate quantitative assessment of the pet trade. This study suggests a possibility that the pet trade might threaten some species and further studies to investigate that possibility are justified. A clearer understanding of the extent of the commercial collection and sale of wild amphibians and reptiles could aid in determining the extent of the threats posed by that commercial use.

Secondly, a review is warranted of the present status of concern species, particularly those currently designated as special concern, along with a review of the current regulations regarding the commercial use of those species. The fact that pet stores sold concern species indicates a possible need for stronger regulations. By comparing a species' current status with information on whether species are sold in pet stores, researchers might determine that regulations restricting commercial collection and sale of some concern species are justified.

Thirdly, an educational program could be developed for the various stakeholders in the pet trade (store owners, employees, suppliers, and customers) to provide correct information on the regulations for commercial use of native herpetofauna and the reasons for those regulations. If the people who could benefit from a sustainable, nonthreatening use of amphibians and reptiles understand how they could benefit from protecting those species, they might become strong supporters for that protection.

These recommendations suggest ways of further understanding the pet trade, the extent of its threat to native herpetofaunal species, and how to lessen the threat. Given the extent of other threats, preventing overcollection for the pet trade might not ensure the survival of amphibian and reptile species, but it might provide populations with an increased chance of survival until problems such as habitat loss can be addressed effectively.

Acknowledgments.—For their assistance in the research and writing of this paper, I thank Al Breisch and Mike Kallaji of the New York State Department of Environmental Conservation; George Robinson, Margaret Stewart, and Thomas Birkland of the University at Albany; my fellow graduate students in the Department of Biological Sciences at the Uni-

versity at Albany; and, finally, the cooperative employees of pet stores and supply companies.

Description of the Tadpole of *Megaelosia goeldii* (Leptodactylidae, Hylodinae) with Natural History Notes

PAULO A. S. NUIN
Museu de Zoologia, USP, Av. Nazareth, 481 04263-000
São Paulo, Brazil
e-mail: nuin@ib.usp.br

The genus *Megaelosia* (Anura, Leptodactylidae) Miranda-Ribeiro, 1923 includes five species of frogs which are little studied because of their scarcity in museum collections and the difficulty of collecting specimens in the field; diurnal adults are wary and plunge into the torrential waters when disturbed (Giaretta et al. 1993).

The tadpoles of this genus have characters in common with the genera *Hylodes* and *Crossodactylus* in the subfamily Hylodinae, such as lateral line well-defined, sinistral spiracle, dextral vent tube, oral disc marginate with a broad anterior gap in the marginal papillae, and tooth row formula 2(2)/3(1). They all live in fast-flowing streams. *Megaelosia* tadpoles are much larger than those of *Hylodes* and *Crossodactylus* and have distinct cranial morphology.

The genus *Megaelosia* is distributed along the Atlantic Rain Forest of southeastern Brazil, especially in the states of São Paulo and Rio de Janeiro. The only known locality of sympatry for two species of this genus is Serra da Bocaina, São Paulo, Brazil, where *M. goeldii* and *M. bocainensis* are found. At every other locality only one species has been recorded, including Teresópolis where the specimens reported herein were collected.

Megaelosia goeldii was described by Baumann (1912), who did not report any measurements for the species. The adult was redescribed by Miranda-Ribeiro (1923, 1926) under the name *M. bufonia* (= *Elosia bufonium*), but the tadpole was only figured in dorsal and lateral views with no further data. Lutz (1930) made a brief description of the tadpole from specimens collected in streams at Petrópolis and Teresópolis, Rio de Janeiro, Brazil and illustrated the dorsal and lateral views but not the mouthparts. Lutz also described the color pattern that he used to compare these tadpoles with *Hylodes* larvae. The later description by Heyer et al. (1990) of a tadpole from Boracéia, Salesópolis, São Paulo, Brazil as *M. goeldii* turned out to be *M. massarti* (Giaretta et al. 1993).

Herein, I describe the tadpole of *M. goeldii* from the type locality of the species, Rio Beija Flor, Teresópolis (22°24'S, 42°69'W), Rio de Janeiro, southeastern Brazil, elevation 910 m.

Material and Methods.—Five tadpoles (Gosner 1960, stages 27, 28, 30, 31, and 35) of *Megaelosia goeldii* were collected in February 2000 and deposited as MZUSP 95879. I compared these topotypic specimens with tadpoles described in the literature (Giaretta et al. 1993; Heyer et al. 1990; Lutz 1930) to confirm their identification. Also *M. goeldii* is the only species of this genus known to occur at the site of collection. The labial tooth formula follows Altig (1970), and all measurements are in millimeters.

The specimen in stage 35 has the following measurements: total length 117.2; body length 48.2; body width 31.8; body height 21.1; eye diameter 3.5, eye-nostril distance 6.4; internostril distance 9.8; and maximal caudal height 28.3. Body ovoid in lateral and dorsal

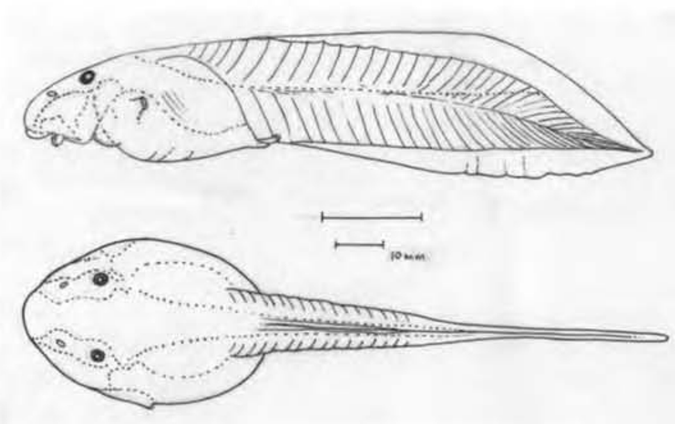

FIG. 1. Lateral and dorsal views of the tadpole of *Megaelosia goeldii* (scale 10 mm).

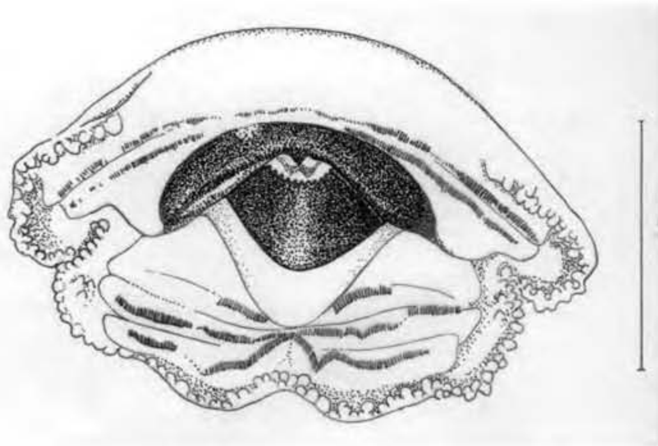

FIG. 2. Mouth parts of the tadpole of *Megaelosia goeldii* (scale 5 mm).

views. Eyes small, dorsolateral, with interorbital distance (from medial eye edge) about four times the eye diameter. Snout rounded, nostrils directed anterolaterally about midway between eyes and tip of snout. Internostril distance (from medial nostril edge) slightly less than interorbital distance. Spiracle short, sinistral with its opening at midbody. Cloacal tube short and broad, opening dextrally. Tail slightly higher than body height and dorsal fin slightly higher than the ventral fin. Both fins thicker proximally. Tip of tail rounded. Oral disc directed anteroventrally with median region of upper labium lacking papillae and lower labium bordered by one row of papillae. One or two rows of marginal papillae near the corners of the disc. Labial tooth row formula 2(2)/(3(1); all rows of teeth of equal length. Beak well developed and serrated (Fig. 2). Lateral line system with 14 lateral branches, 7 on each side of the body and tail (Fig. 1): angular, anterior oral, infraorbital, longitudinal oral, posterior infraorbital, supraorbital, ventral. The lateral line system is similar to that figured in Miranda-Ribeiro (1926, as *M. bufonia*).

In life, dorsum brown with irregular dark spots, ventral surface pale, terminal part of tail lighter brown with dark, clustered blotches. Preserved specimens have a dark brown dorsum and a pale ventral surface; fins are pale brown with small dark spots (0.2–0.5 mm). Tail musculature light brown with clustered blotches. Figs. 1 and 2 depict the largest specimen obtained.

Natural History.—Tadpoles and adults of *Megaelosia goeldii* were observed from the type locality along the Rio Beija-Flor, Teresópolis, Rio de Janeiro, a tributary of Rio Paquequer. Although both rivers were searched inside the borders of the Parque Nacional da Serra dos Órgãos, I observed specimens (adults, juveniles, and tadpoles) only along a 300 m section of the river outside the borders of the park. Over three days, from 0900 to 2100 h, the density of adults varied from 8 to 12 specimens sighted on large emergent rocks in the Rio Beija-Flor. At Rio Paquequer I saw one dead adult, but local inhabitants claim that these frogs are observed daily. The adults are wary and jump into the water when disturbed and were observed only during the day; at night they hide under rocks or might be found on low vegetation on the stream banks (W. R. Heyer, pers. comm.).

Both banks of the Beija-Flor are bordered by masonry houses and walled with bricks lacking vegetation at a distance of ca. 200 m beyond the park borders. At Rio Paquequer, the left bank is walled and the right bank is protected by the park border. In some places people have built dikes in the riverbed to make swimming pools.

The greatest density of tadpoles occurred during the night in these swimming pools, seemingly having emerged from under the rocks to feed. During the day until sunset few tadpoles were observed in the same places the adults were sighted.

Acknowledgments.—This work was partially supported by FAPESP (grant no. 98/03741-0). I would like to thank to W. R. Heyer for the kind comments and revision of this work and Francisca C. do Val for preparing the figures.

The Identification of New Specimens of *Vipera* from Trabzon, Turkey with Affinities to *Vipera barani* and *V. pontica*

BİLAL KUTRUP
Karadeniz Technical University, Faculty of Arts and Sciences
Department of Biology, 61080 Trabzon, Turkey
e-mail: kutrup@ktu.edu.tr

The taxonomic identification and distribution of the poorly known *Vipera barani* and *V. pontica* have been problematic because of the limited number of specimens available for study (Baran et al. 2001). *Vipera barani* Böhme and Joger, 1983 was described from a single melanistic female from Sapanca, north of Adapazarı at the southwest coast of the Black Sea. Its distribution was expanded to the southeast coast of the Black Sea with the reports of four specimens from Rize and Giresun provinces (Frazen and Heckes 2000) and two additional specimens from the high mountain slopes of Çaykara (1950 m) in Trabzon province (Baran et al. 2001). No specimens have been collected from regions between these areas, but Baran et al. (2001) speculate that its

distribution might extend along the intervening mountains bordering the Black Sea.

The two specimens of *Vipera barani* from Çaykara in Trabzon province showed intermediacy in their morphology and color pattern when compared to *V. pontica*, leading Baran et al. (2001) to question the validity of the latter species. *Vipera pontica* Billing, Nilson, and Sattler, 1990 was described from two specimens from the Coruh Valley in Artvin province and diagnosed from *V. barani* by having an upturned snout and more loreals. Additional specimens of *V. pontica* were reported from Çamlıhemşin in Rize province, extending its range to the west to overlap that of *V. barani* (Baran et al. 1997, 2001).

A total of seven new specimens, from four lowland Black Sea coast locations in Trabzon province, with affinities to *Vipera barani* and *V. pontica*, are reported here. These specimens are compared to *V. barani* and *V. pontica* to determine their identity and to shed light on the problems associated with the diagnosis of these species. The new material was collected from April to September in both 1999 and 2000 and deposited at Karadeniz Technical University (ZKTU). A male (ZKTU 7/1999-1) was collected from Ballıca, ca. 63 km E of Trabzon. At Sugeldi, another male (ZKTU 7/1999-2) was collected near the Baltacı Stream area, 5 km E of Ballıca. Four specimens (two males and two females [ZKTU 7/1999-3-6]) were collected from Çamlık, 68 km W of Trabzon. Of these, one female was large (> 600 mm total length) and the remaining were small (< 200 mm total length). The last specimen collected was a female (ZKTU 8/2000-1) from Çınarlı, 1 km E of Trabzon. The Ballıca, Çınarlı, and Sugeldi specimens were captured near tea plants (*Camellia sirennis)*, while the Çamlık specimens were captured on the short grassland with oak (*Quercus* sp.*)*, alder (*Alnus* sp.), and hazelnut (*Corylus* sp.) trees.

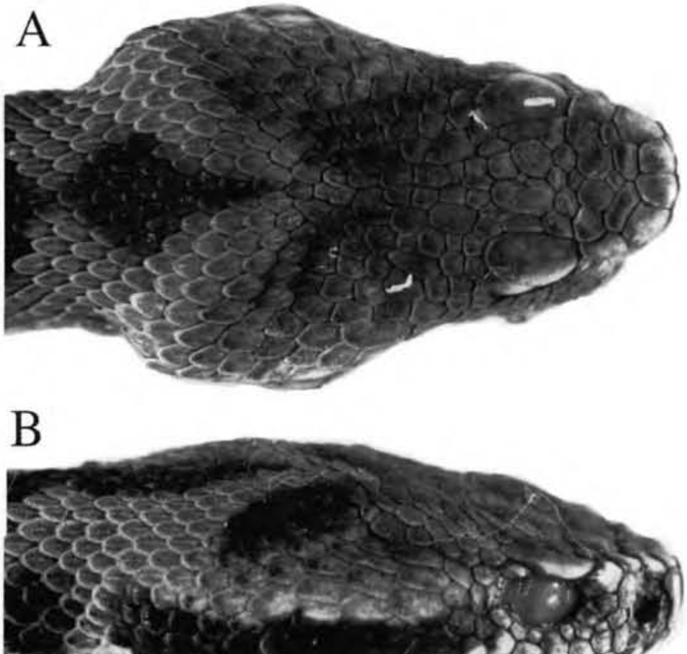

FIG. 1A. Dorsal view of head of the male from Ballıca (ZKTU 7/1999-1). B. Lateral view of same specimen.

FIG. 2. Dorsal view of a normally colored male from Ballıca (ZKTU 7/1999-1).

This new material was compared to five specimens of *Vipera barani* and two specimens of *V. pontica*. Fourteen characters were analyzed, including those traditionally used to separate *V. barani* from *V. pontica* (Table 1). Pattern and coloration of the newly collected specimens (1 melanistic, 6 typically colored) were examined in life subsequent to preservation. Additional data were taken from the literature and another nine specimens collected from Çamlıhemşin, Giresun, and Çaykara that have been previously reported (see Table 1; Baran et al. 2001 and references therein).

The ventral scale number of the specimens from the lowland Black Sea localities (Ballıca, Sugeldi, Çınarlı, and Çamlık) ranges from 140 to 149. With the exception of the two female specimens from Çamlık (both with 149 ventrals), ventral scale numbers fall within the range of specimens identified as *Vipera barani* (142–145) and *V. pontica* (142–147). The number of subcaudals is higher in all males (33–38) compared to females (29–31) and corresponds to the increased tail length to total length in males (0.15–0.17) compared to females (0.11–0.13). Gender specific differences of the new specimens fall within the range of previously known specimens (also see Baran et al. 2001: Table 1).

Two apical scales are present over the rostral scale in all

TABLE 1. External morphology of the Trabzon viper specimens collected from lowland Black Sea coast localities (Ballıca, Sugeldi, Çınarlı, and Çamlık) and related taxa (*Vipera barani* from Adapazarı and Silifke, *V. pontica* from Artvin and the specimens from Çamlıhemflin, Giresun, and Çaykara). Asterisk (*) denotes characters not visible because of damaged specimen.

Characters	Ballıca 1 ♂	Sugeldi 1 ♂	Çamlık 2 ♀	Çamlık 2 ♂	Çınarlı 1 ♀	*V. barani* (N = 5)	*V. pontica* (N = 2)	Çamlıhemflin (N = 5)	Çaykara (N = 2)	Giresun (N = 2)
Tail length (mm)	82	83	32–69	38–46	78	56–69	30 (31)	—	52–57	—
Total length (mm)	518	543	186–627	172–197	634	550	254–277	—	444–590	—
Ventral	140	141	149	140–145	146	142–145	142–147	140–145	142	142–146
Subcaudal	37	33	30/31	37/38	29	26–37	32/36	30–38	28/29	30–36
Mid-body scales	21	21	21	21	21	21–23	21	21–23	21	21
Apicals	2	2	2	2	2	2	2	2	1(2)	—
Canthals	2/2	2/2	2/2	2/2	2/2	2/2	1–1.5	2/2	2/2	2/2
Rostral index	1.18	1.05	1.05–1.07	1.08–1.16	1.10	—	1.05–1.40	—	1.12–1.24	—
Loreals	5/5	5–*	4–5	4–5	4/5	3–6	6–7	4–11	4–5	4–5
Supralabials	9/9	9–*	8–9	9/9	9/8	9–10	9–9	8–9	8–9	8–10
Sublabials	11/11	11/11	10–11	10–11	10/11	10–12	11–12	10–13	9–11	11–12
Circumoculars	13/12	10/10	9–10	8–11	11	10–14	9–10	10–12	8–9	9–11
Crown scales	22	25	22–25	24–33	26	23–40	34	25–33	18–24	14–21
Zig-zag bands	67	*	62–65	64–67	57	—	51–58	—	48(49)	—

specimens (Fig. 1a), with no remarkable difference between their size (Baran et al. 2001). Similarly, the numbers of mid-body scales, canthals, supralabials, sublabials, and circumoculars show little variance or a high degree of overlap between the specimens examined (Table 1). The number of crown scales (intercanthals + intersupraoculars) ranges from 22 to 36 for lowland Black Sea specimens. Specimens of *Vipera pontica* (34), *V. barani* (23–40), Çaykara (18–24), and Çamlıhemşin (25–33) have overlapping crown scale counts, while the two specimens from Giresun province (14–21) have a lower range (but, overlap Çaykara).

The number of loreal scales on each side of the head (Fig. 1b) ranges between 4 and 5 for the lowland Black Sea specimens, which overlap the ranges of *Vipera barani* (3–6), Çamlıhemşin (4–11), Çaykara (4–5), and Giresum (4–5). *Vipera pontica* have a slightly higher range (6–7), but overlaps *V. barani* and specimens from Çamlıhemşin.

The single melanistic male from Sugeldi shows similarities with the melanistic female specimen collected from Çaykara (Baran et al. 2001: Fig. 2). Both have whitish blotches on upper and lower labials and whitish spots of different sizes on the ventral surface of the head. The melanistic male has whitish supralabials edged in black compared to a yellowish-white of the female.

The six typically patterned specimens have a greyish brown ground color with fragmented blackish zig-zag bands (Fig. 2). These *aspis*-like zig-zag bands are similar to the specimens from Çaykara and Çamlıhemşin and *Vipera pontica* (Baran et al. 2001; Billing et al. 1990), as opposed to the unfragmented *berus*-like pattern seen in *V. barani* (Baran et al. 2001; Joger et al. 1997). The lowland Black Sea specimens have a high number of zig-zag bands (62–67) compared to *V. pontica* (51–58) and the high mountains of Çaykara (48–49). The number of zig-zag bands has been correlated to altitude in *V. dinniki*, with higher numbers of bands increasing with altitude (Nilson et al. 1994, 1995; Hoggren et al. 1993; Kutrup 1999). The opposite trend seems to be true with these specimens.

Dark vertical blotches run along the lateral sides of the body and do not connect with the zig-zag bands. Two black bands extend diagonally from the posterior end of the parietal area to the sides of neck (see Fig. 1b), similar to specimens from Artvin, Adapazarı, Çamlıhemşin and Çaykara. The sides of the body of small specimens have white spots extending to the level of the anal plate, while larger individuals have spots to the mid-body. The ventral ground color is black and contain no whitish spots under the tail. The tips of the tails are yellowish in all specimens.

The lowland Black Sea specimens have blunt and expanded snouts, a characteristic of the *berus* complex (see Fig. 1). In comparison, specimens from the Artvin province used in the description of *Vipera pontica* and those collected from Çamlıhemşin have an upturned snout (Baran et al. 2001; Billing et al. 1990).

The addition of seven new specimens from Trabzon province provides useful insights into the variation used to separate the species *Vipera barani* and *V. pontica*. Baran et al. (2001) reported on two specimens from the high elevation location at Çaykara, along with additional material from Artvin, and found intermediacy in the variation used to diagnose the two. Similarly, the seven specimens from the lowland Black Sea coast locations show intermediacy as well. The color pattern in six of the new specimens is similar to *V. pontica*, whereas the melanistic specimen resembles *V. barani*. In addition, our present knowledge of the morphological variation further diminishes the distinctiveness of the two species (Table 1). Baran et al. (2001) recommended the synonymy of *V. pontica* with *V. barani*, which is further supported here. It remains a possibility that *V. barani* has differentiated at the subspecific level along the distribution of the two species (Baran et al. 2001), but, a characterization of this variation will require additional material and more sensitive molecular techniques. Additional specimens of these poorly known vipers collected from throughout their distribution will further clarify the variation seen in *V. barani*.

The Thermochron: A Truly Miniature and Inexpensive Temperature-Logger

MICHAEL J. ANGILLETTA JR.
and
AARON R. KROCHMAL
Department of Life Sciences, Indiana State University
Terre Haute, Indiana 47809, USA
e-mail (MJA): m-angilletta@indstate.edu

Miniature temperature-loggers (e.g., HOBO, Watchdog) have become valuable tools for herpetologists, and biologists in general. Being lightweight and self-contained, miniature temperature-loggers make it easy to record simultaneously temperatures at separate sites. Certain models are waterproof and can be attached to or implanted in large organisms, providing detailed profiles of body temperature that are otherwise difficult to obtain (e.g., Butler and Woakes 2001; Litzgus et al. 1999). In some microhabitats, temperature-loggers can even be used to estimate operative environmental temperatures (Vitt and Sartorius 1999). Miniature temperature-loggers are accurate and reliable under field conditions and are generally easier to program and deploy than larger, more expensive systems (Mueller and Rakestraw 1995). Although the use of miniature temperature-loggers has increased rapidly in the last decade, reductions in the size and cost of these devices have not kept pace.

Recently, a novel temperature-logging device has emerged that could enhance studies of behavioral and physiological ecology. The Thermochron iButton, manufactured by Dallas Semiconductors (Dallas, Texas, USA), is a remarkably small and light temperature-logger than meets or exceeds the specifications of temperature-loggers that are commonly used by biologists. Each Thermochron is a mere 5.9 mm thick and 17.4 mm in diameter, and has a mass of 3.1 g. The outer casing is stainless steel, permitting the unit to function normally during complete submersion in water. The Thermochron is powered by an non-replaceable, internal battery that provides approximately 10 years of service (or one million readings). The manufacturer specifies a resolution of 0.5°C and an accuracy of ± 1°C within the operating range of –20° to 85°C. The thermochron was developed primarily as an inexpensive tool for commercial shipping companies to document that perishable goods have been stored and transported within an acceptable range of temperatures. Current pricing is approximately US $14 per unit, and discounts are available for purchases of 25 or more units. Thus, the Thermochron is a high-performance temperature-logger that is approximately 10% of the cost of similar products.

Thermochrons are launched (or "missioned") using free software downloaded from the manufacturer's website and hardware included in a startup kit (US $25). The interface between a computer (Macintosh or PC) and a Thermochron is established with an iButton reader (Blue Dot Receptor, Model DS1402D-DR8), which attaches to a serial port. The software (32-Bit iButton-TMEX Runtime Environment) provides an intuitive interface that allows one to toggle among windows enabling one to mission a logger, display the status of the current mission, and report output from a mission in progress. A mission "wizard" provides an easy to follow, step-by-step process of starting a mission. Advanced features and ranges of settings are almost identical to those offered for competing brands of temperature-loggers (e.g., HOBO Temp loggers used with BoxCar Pro 4.5, Onset Computer Corporation). For example, the output can be obtained in the form of a text file or a histogram of temperatures, and each file is marked with a 48 bit serial number that identifies the logger generating the data. Each mission can record up to 2048 data points, at rates ranging from one point per min to one point per 255 min. The start of the mission can be delayed up to 45 days, so that the user has time to position the Thermochron prior to the onset of data collection.

Thermochrons also possess several unique features. Firstly, the Thermochron can add temperatures to the histogram after the maximum number of time-stamped data points have been stored; therefore, the mean temperature and its variance can be obtained for durations that far exceed the duration of the mission. Secondly, Thermochrons are equipped with an alarm feature that permits monitoring the number and duration of deviations from minimum and maximum temperatures (set by the user). The alarm feature is extremely useful for applications such as monitoring the occurrence of lethal temperatures in nests or hibernacula. Lastly, the Thermochron features 512 bytes of memory that enables the user

the tube entrance (Fig. 2B). To elicit movement in the desired direction, prodding is best directed towards a crocodile's posterior (e.g., base of tail, thigh) (pers. obs.). Our crocodilians bite at poles that approach or come in contact with their heads, rather than move in the desired direction. Juvenile *Crocodylus porosus* x *siamensis* entered the pipe readily, and most captures were accomplished in < 5 minutes. Once a crocodilian enters the pipe, the entrance side is quickly pulled up and out of the water by means of an attached capture rope (Fig. 2C). The crocodile is thus momentarily in an inverted vertical position and is unable to back out of the smooth, water-filled, pipe. The entrance is quickly sealed with the sliding door and secured. Finally, the pipe is pulled completely out of the water by means of the second load bearing rope handle (Fig. 1; Fig. 2C). Drainage slits allow water to quickly drain from the pipe (Fig. 1). The crocodile is then safely contained in a dark, wet, and smooth pipe. We believe that these characteristics provide a relatively non-stressful environment for the animal and prevent physical injury. A minimum of two people are required to trap a juvenile crocodilian in this fashion, although more may be required to lift and transport the pipe and its occupant. At Shark Reef, the entire process takes place with staff standing along the edge of an eight-foot deep exhibit pool. Although this technique reduces stress during capture and transport, confined crocodilians should not be exposed to excessively warm areas and/or direct sunlight, as thermal stress can also be fatal. To release a crocodilian, the pipe entrance is simply oriented towards a body of water and the door is removed. Tilting the pipe causes the crocodilian to slide out tail first into the water.

The Crocodilian Capture Tube has many advantages over current capture methodologies: (1) No direct physical contact is required between the crocodilian and handlers; (2) there is no need for securing the crocodilians jaws; (3) specimens can be captured underwater with ease; (4) no stressful thrashing or rolling behavior is exhibited by captured crocodilians; (5) there is no longer a need to cover a crocodilian's eyes, as it is in a dark tube; (6) the device serves as a safe short-term holding and on-site transport container; (7) no sedatives are required to capture and/or transport an animal; and (8) the crocodilians body is evenly supported during transport.

Acknowledgments.–We thank Adam Britton, Andy Odum, and one anonymous reviewer for helpful comments on earlier drafts of this manuscript. We would also like to thank Michael Eaton for the splendid illustrations. Finally, we acknowledge Christopher Blanar for his help in obtaining an elusive reference.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 33, Number 1 (March 2002). However, please take note of the updated information below.

Current section editors: **Marc P. Hayes** (amphisbaenids, crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; cpainter@state.nm.us); **Gordon W. Schuett** (snakes; gschuett@asu.edu); and **James Harding** (turtles; hardingj@pilot.msu.edu). Electronic submission of manuscripts is required (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Authors without the ability to send manuscripts electronically may supply hard copy instead. Figures can be submitted electronically as JPG files, although higher resolution TIFF or BMP files will be requested for publication. If figures cannot be provided in this format, you may send them to the section editor for scanning. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ukans.edu/~ssar/HRinfo.html.

CAUDATA

AMPHIUMA MEANS (Two-toed Amphiuma). **OVERLAND MIGRATION**. *Amphiuma means* is a large aquatic salamander with reduced limbs and an eel-like appearance. Amphiumas inhabit relatively shallow, lentic water habitats and water levels in these habitats often fluctuate seasonally and/or annually. During periods of drought, amphiumas are known to aestivate in burrows within organic sediment of dry lake bottoms (Knepton 1954. Copeia 1954:68; Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing Co., Auburn, Alabama). There are no published accounts of *A. means* traveling overland, although the possibility of overland migration/dispersal has been suggested (Snodgrass et al. 1999. Copeia 1999:107–113). Here, I report overland migration of an adult amphiuma from a drying lake during a drought.

Lake Jackson in Leon County, Florida, USA is a 1620 ha sinkhole lake that dried to 10% of normal surface area in 1999–2000 during a prolonged drought in northern Florida. In order to monitor the mass migration of reptiles and amphibians from the drying lake, I constructed an 853-m drift fence along U.S. Highway 27N adjacent to the northwest part of Lake Jackson. Animals were migrating to a 7-ha lake (Little Lake Jackson) that did not dry located immediately to the west of U.S. 27. On 10 June 2000 at 1100 h, I found a dead, partially desiccated adult male *A. means* (SVL 40 cm, TL 79 cm) at the drift fence. The body was positioned perpendicular to the fence with the snout touching the fence. The amphiuma apparently moved during the previous night as it was not observed at the fence at 2030 h on 9 June. There were no signs of injury that might suggest it was carried there by a predator. There were clear skies 9–10 June and full sunshine on the morning of 10 June; the only moisture was morning dew on dense vegetation.

There are two possible scenarios to describe the terrestrial movement of this amphiuma: either it migrated from a drying lake pool or it emerged from an aestivation burrow. The latter is unlikely as there was no rainfall since 5 June 2000 (0.05 cm) and, therefore, probably no trigger mechanism that might stimulate emergence from aestivation in an area of lake bottom that was dry for 1–2 years and covered with terrestrial vegetation. Although most amphiumas probably aestivate under organic sediment in the littoral zone of drying lakes (Aresco 2001. Herpetol. Rev. 32:32–33), some individuals may remain active in slowly receding water with little or no aquatic vegetation. Under these conditions, the increased

predation risk posed by dense concentrations of fish, turtles, and wading birds and increased water temperatures may eventually force migration.

The nearest drying pool remaining at Lake Jackson was 250 m to the east of where the amphiuma was found. The water depth of this pool was < 0.25 m and it dried completely by 18 June 2000. If the amphiuma left this drying pool, it would have first moved 50 m over dry, cracked mud and then through maidencane (*Panicum hemitomon*), smartweed (*Polygonum densiflorum*), and dog fennel (*Eupatorium compositifolium*) growing over the dry lake bottom. The location and position of the amphiuma indicates that it was moving in the same direction as migrating turtles (e.g., *Pseudemys floridana*), frogs (e.g., *Rana grylio*), and snakes (e.g., *Seminatrix pygaea*) to Little Lake Jackson located 600 m from the drying pool. This observation suggests that *Amphiuma means* may possess an ability to detect water from some distance away and may attempt terrestrial migration under a unique set of environmental conditions.

ENSATINA ESCHSCHOLTZII OREGONENSIS* x *PICTA (Oregon x Painted Salamander Intergrade). **REPRODUCTION / BROODING BEHAVIOR.** *Ensatina eschscholtzii* is the most widespread plethodontid in western North America, with a range extending from southern British Columbia to extreme northern Baja California (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.). However, little is known about natural intergrade brooding behavior in northern California. Most reports have dealt with cases from the San Francisco Bay region of California and Coos Co., Oregon (Stebbins 1954. Univ. California Publ. Zool. 54:47–124) and Washington, where specimens were removed from their natural environment to a laboratory or preserved (Norman and Norman 1980. Bull. Chicago Herpetol. Soc. 15:99–100; Jones and Aubry 1985. Herpetol. Rev. 16:26; Norman 1986. Herpetol. Rev. 17:89).

An extended period of observation of the brooding behavior of a single adult female *Ensatina eschscholtzii oregonensis* x *picta* intergrade, and the eventual hatching of her clutch is reported herein. On 2 June 2001, the brooding female intergrade was found encircling a cluster of cream-colored ova at a semi-rural, residential area at Westhaven, California (T8N R1E SW1/4 Sec. 31; elev. ca. 100 m). The site was within the coastal redwood region of Humboldt County. The brooding chamber was located under a piece of downed woody debris (53 cm long x 25 cm wide x 30.5 cm high) which rested on the forest floor. Litter components under the object consisted of redwood (*Sequoia sempervirens*) and Sitka spruce (*Picea sitchensis*) needles, introduced English ivy (*Hedera helix*) roots, and decomposing organic matter. The forest canopy consisted of old-growth Sitka spruce and second growth redwood, with few red alder (*Alnus rubra*) and cascara buckthorn (*Rhamnus purshiana*) present in the understory. Old-growth redwood stumps are also present in the immediate vicinity.

The brooding female measured 5 cm SVL (measuring to the anterior edge of the cloaca), ca. 9.2 cm TL, and possessed 13 costal grooves, brassy coloration on the snout, and the upper half of her eyes contained gold flecking (as in *Ensatina eschscholtzii xanthoptica* [see Stebbins 1985]). Her dorsal coloration was brown as in *E. e. oregonensis*, with fine yellow specks; the ventral surfaces were translucent light cream and brownish with shades of blue and gray. Her axillae and rear limb insertions were bright yellow and the entire tail was blotched with light yellow markings on brown as in *E. e. picta*. Her tail tip and toes were complete. The egg cluster consisted of ca. 11–17 ova and was light cream-colored and brownish. When first observed, the cluster was covered with fine particulate organic matter and the ova did not appear translucently gelatinous.

The site was revisited periodically over a span of the next 18 wks. The brooding female was observed in attendance with the egg cluster upon each observation, prior to 5 October 2001, and usually with her head and tail wrapped around the cluster, with her body and pulsating gular region in contact with the eggs. The female appeared to have moved the egg cluster ca. 10 cm from its original position around the date of 23 June 2001, similar to a laboratory observation made by Stebbins (1954:91, *ibid.*). At ca. 2000 h on 23 June 2001 soil temperature was 13.2°C; air temperature was 12.6°C at 2015 h and the cluster chamber measured ca. 6 cm x 4 cm x 2 cm. It was generally apparent that the brooding female would remain motionless unless disturbed, then she would rearrange herself around the cluster.

By 1 August 2001, the eggs had increased in diameter from ca. 5 mm to 7 mm; very dark brown to black shading was perceptible in one hemisphere of each ovum, indicating embryonic development was occurring. Two weeks later, as the dark region grew even darker, the eyes of embryos could be clearly seen through the outer membranes of the ova. Ova now measured 8 mm in diameter.

By 1 September 2001 the eggs had become more developed, appearing more translucent and clearly gelatinous, having lost the dull cream color; the ova had become even more fully hemispherically shaded as embryos reached pre-hatch maturation. Photographs were taken to complement those taken 2 June, the date of initial discovery. The brooding female appeared slightly thinner, possibly due to desiccation from an unseasonably dry summer, with rainfall levels approximately 23 cm below normal for the area (NOAA data).

Finally, on 15 September 2001, after the first hard rain of the summer, and fifteen weeks post-discovery, all ova hatched. A total of 11 hatchlings were counted in the brooding chamber, each measuring ca. 2.2 cm TL. The brooding female was still in attendance and had five hatchlings on top of her back and two under her forelimbs. The remaining hatchlings were in front of her, still inside the brooding chamber, or beside her tail. The bluish-gray blotched hatchlings were active and sought cover immediately under moist leaf litter when disturbed.

The site was inspected again on 23 September 2001 and the adult female was still in attendance with a single hatchling on her head, four others on her back and others next to her tail. Now, the female appeared larger with moist, shiny skin. Again, the hatchlings were active when startled and moved quickly to find cover. Two days afterward the site was again photographed and nine hatchlings were present with the female.

On 5 October 2001 the female was not present for the first time since 2 June 2001. Six hatchlings remained clustered together in a

ball-shaped configuration, they each actively sought cover, moving up to 4–5 cm in just a few seconds. The next day (6 October) four hatchlings remained and one California slender salamander (*Batrachoseps attenuatus*) sub-adult, in coiled position, was present 16 cm away from those hatchlings. Finally, on 14 October 2001 no salamanders were present at the brooding micro-site.

Samantha J. Hadden, Thomas A. Kirk, and Alexander Galeone assisted documenting these observations with photographs. In addition we thank the landowners, John and Carol Wiebe, for their support and enthusiasm for this project and for permission to conduct observations on their property.

HEMIDACTYLIUM SCUTATUM (Four-toed Salamander). **RECORD SIZE**. Conant and Collins (1998. Peterson Field Guide to Reptiles and Amphibians of Eastern and Central North America. 3rd Ed. Expanded. Houghton Mifflin, Boston, Massachusetts. xviii + 616 pp.) report maximum size for *Hemidactylium scutatum* as 4.0 in (102 mm) total length. Here we report a larger individual, 45.1 mm SVL and 113.6 mm TL. This individual was found on 23 October 2001 at Toft Point State Natural Area, Door County, Wisconsin, USA. After measurement, the salamander was photographed and released. The photograph (136-s) is deposited at the Richter Museum of Natural History, University of Wisconsin, Green Bay.

Submitted by **STEVEN J. PRICE** and **JEANETTE M. JASKULA**, Cofrin Arboretum Center for Biodiversity, University of Wisconsin, Green Bay, Green Bay, Wisconsin 54311, USA.

RHYACOTRITON VARIEGATUS. (Southern Torrent Salamander). **PREDATION**. On 19 June 1996 at ca. 1400 h I observed a sub-adult northwestern garter snake (*Thamnophis ordiniodes*) in the process of consuming a larval southern torrent salamander (*Rhyacotriton variegatus*) at a small east-facing seep at an elevation of 1049 m in Del Norte County, northwestern California. The seep ran adjacent to and through a culvert under U.S. Forest Service Rd 17N05 (T17N R3E SW1/4 Sec. 55). The seep drains the headwaters of the Siskiyou Fork of the Smith River at variable slopes of ca. 60–80%. Surface flow at the seep site was steady and constant during observations and the seep appeared permanent with heavy moss growth enclosing cobbles and gravels as well as larger more embedded regolith and unembedded finer sediments.

At the time of observation the head of the salamander was fully-engulfed by the snake. The snake was disturbed by my presence. When secured by hand the snake promptly regurgitated the salamander. In captivity, the snake later re-consumed the previously injured salamander within 24 h. Another larval *R. variegatus* from the same seep, also available as prey, was not consumed during the same time period.

The consumed larval *R. variegatus* measured 41.0 mm TL with incomplete tail tip, SVL was 31.0 mm (measured to the anterior edge of the cloacal opening), and a total mass of 0.8 g. The snake measured 130.0 mm TL, 73.0 mm SVL, and had a mass of 3.2 g. Vouchers (BRN 1996-#016A and B) will be deposited in the Humboldt State University Vertebrate Museum Collection, Arcata, California, and were taken under California State Scientific Collecting Permit #9030 issued to the author.

Although *T. ordinoides* is considered a mostly terrestrial species (Brown et al. 1995. Reptiles of Washington and Oregon. Seattle Audubon Society, Seattle, Washington. 176 pp.; Stebbins 1985. A Field Guide to Western Reptiles and Amphibians. 2nd Ed. Houghton Mifflin Co., Boston, Massachusetts. 336 pp.), the snake reported herein was discovered while partially submerged within the flow of the seep during the initial consumption of the larval *Rhyacotriton*. Water temperature was 9.1°C and air temperature was 21.3°C at ca. 1500 h.

Unfortunately, a significant mass-wasting event occurred prior to spring 1997 observations at the site. This slide resulted in a dramatically altered seep course. Limited observations in 1997 did not detect any *Rhyacotriton variegatus* at the site after the slide had occurred (pers. obs. and unpubl. data). To my knowledge this is the first report of *T. ordinoides* preying upon a larval *Rhyacotriton* in a natural setting, although garter snakes have previously been suspected to possibly prey on *Rhyacotriton* (Nussbaum et al. 1983. Amphibians and Reptiles of the Pacific Northwest. Univ. of Idaho Press, Moscow. 332 pp.).

I thank Hartwell H. Welsh, Jr. (Redwood Sciences Laboratory, Arcata, California) for encouraging me to report these observations. Welsh and Karen L. Pope reviewed a draft and provided helpful comments that improved this manuscript.

SIREN INTERMEDIA NETTINGI (Western Lesser Siren). **MIGRATION and LOCOMOTION**. On 13 and 14 April 2001, a total of 15 (six on 13 April and nine on 14 April) *Siren intermedia nettingi* were observed at Nashoba Park (Germantown, Shelby County, Tennessee, USA; 35°07'N, 89°48'W). The sirens were migrating upstream from one pond to another through a large (2 x 3 m) concrete culvert ca. 40 m long. The flow of water through the culvert is typically a trickle, but precipitation on 11 and 12 April resulted in a rapid flow of water (4–6 cm deep) from the upper to the lower pond. The salamanders were observed at night moving upstream by slowly crawling along the flat bottom of the concrete culvert, relying heavily upon the use of their forelimbs. Any individual that was disturbed by an observer would immediately release its grip on the concrete and be quickly washed downstream by the swift current. The observed difficulty in swimming against the current suggests that the migration may not have been possible without use of the forelimbs. Subsequent observations of a captured *S. i. nettingi* in captivity also suggest that the limbs are vital to the salamander's locomotion. These observations provide evidence contrary to the suggestion by Cochran and Goin (1970. The New Field Book of Reptiles and Amphibians. Putnam, New York. 359 pp.) that the forelimbs are useless in locomotion.

Our field observations coincide with dates reported for oviposition and nesting of *S. i. intermedia* in the Carolinas and *S. i. nettingi* in Arkansas (Petranka 1998. Salamanders of the United States and Canada. Smithsonian, Washington, D.C. 587 pp.). Thus, the animals we observed may have been searching out oviposition sites. The culvert separating the upper and lower ponds in Nashoba

Park could therefore act to limit the available sites for animals on either side. The isolation effect of the culvert would, of course, depend on the frequency of precipitation events during the reproductive period that are sufficient to permit migration.

ANURA

ACRIS CREPITANS BLANCHARDI (Blanchard's Cricket Frog). **PREDATION**. Although spider predation of anurans is frequently documented (Mitchell 1990. Herpetol. Rev. 21:89–90; McLister and Lamond 1991. Can. Field-Nat. 105:574–575; Johnson 1996. Herpetol. Rev. 27:140; Rogers 1996. Herpetol. Rev. 27:75), we report herein, and to our knowledge, the first account of a wolf spider, *Hogna helluo*, feeding on the Blanchard's cricket frog, *Acris crepitans blanchardi*.

The documentation of this incident is of particular importance because Blanchard's cricket frogs are currently touted as a species in decline in North America, having been extirpated in Canada and thought to be extirpated in Minnesota (Froom 1982. Amphibians of Canada. McClelland and Stewart Ltd., Toronto 120 pp.; Green 1997. Herpetol. Conserv. 1:291–308; Bishop and Petit 1992. Can. Wild. Serv. Occ. Pap. 76:1–120; Oldfield and Moriarty 1994. Amphibians and Reptiles Native to Minnesota. Univ. Minnesota Press, Minneapolis, 237 pp.; Greenwell et al. 1996. Aquaticus 26:48–54; Harding 1997. Amphibians and Reptiles of the Great Lakes Region. Univ. Michigan Press, Ann Arbor, 378 pp.). Although documentation of this species' decline can be traced back to the 1970s, no clear understanding of the factors contributing to this decline exists (Vogt 1981. Natural History of Amphibians and Reptiles of Wisconsin. Mil. Pub. Mus., Milwaukee 205 pp.; Morell 1999. Science 284:728–731). Thus, descriptions of cricket frog mortality may shed insight into causative factors of their decline and offer implications for their conservation.

We observed an adult wolf spider preying upon a juvenile Blanchard's cricket frog on 20 July 2000, between 1500 and 1510 h along the edge of a semi-permanent wetland at the Mary Gray Bird Sanctuary in Connersville, Indiana, USA (39°35'03"N, 85°13'44"W). We observed that the spider's fangs had punctured the dorso-posterior region of the frog. The frog struggled briefly, appeared weakened, and could not free itself. After ca. 5 min, the spider released the frog. A large area of necrotic tissue was immediately visible where the bite occurred. Following several putative attempts to flee, the frog appeared immobilized yet periodically opened its mouth as if gasping for air. On the following day, we returned to the wetland and found the frog's desiccated corpse intact and in the same position as we had left it.

It is not clear whether the spider captured the frog by attacking it or whether it was scavenging. Although wolf spiders have been observed scavenging the remains of dead prey in laboratory settings (Nentwig 1987. Ecophysiology of Spiders. Springer-Verlag, New York, 448 pp.), it is well known that these vagrant, generalist predators usually ambush or actively hunt their prey (Foelix 1996. Biology of Spiders. Oxford University Press, Oxford, 330 pp.). Although we archive a single feeding episode of *A. c. blanchardi* by *H. helluo*, perhaps these syntopic species interact more often than is presently apparent. Investigative endeavors into the impact that these species may have on one another may be valuable to our understanding of their biology, and to the decline of *A. c. blanchardi*.

We thank Gail Stratton and Pat Miller for their assistance in identifying the spider. Also thanks to Deanna Barricklow of Mary Gray Bird Sanctuary and the Indiana Audubon Society for allowing us to conduct amphibian research on the Sanctuary grounds.

BOOPHIS ALBILABRIS (NCN). **DEFENSIVE BEHAVIOR.** During a herpetological survey along a small forest stream in January 1996 at Anjanaharibe-Sud Massif (Analabe Valley; 14°45.3'S, 49°30.3'E), NE Madagascar, I found a great number of *Boophis*

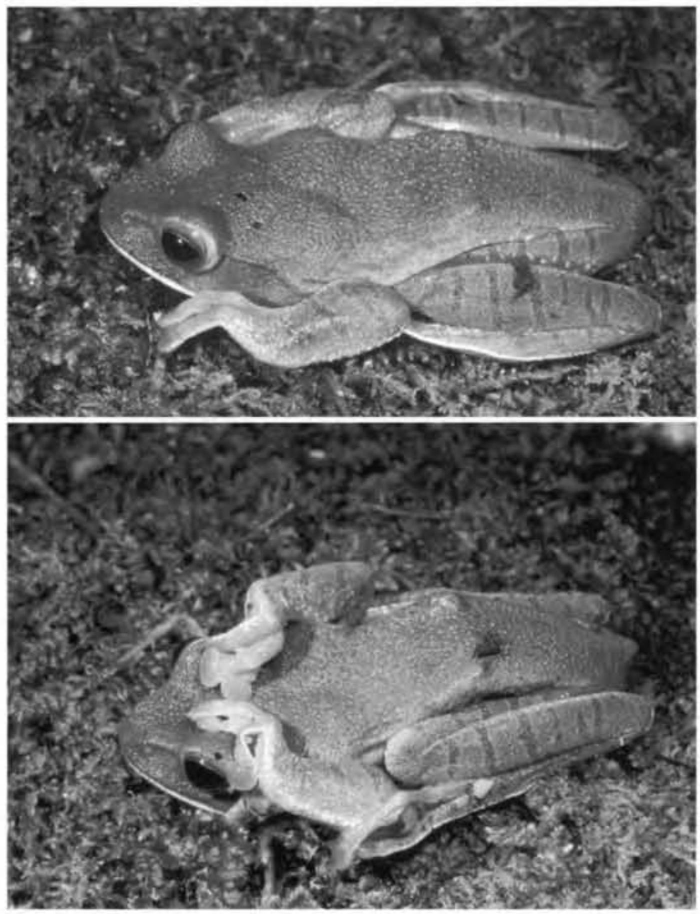

FIG. 1. Top: typical resting position of adult male *Boophis albilabris*. Bottom: defensive posture, with forearms covering the head and eyes. Specimen photographed at Anjanaharibe-Sud Massif, NE Madagascar.

albilabris (Amphibia, Mantellidae), a treefrog typical of the eastern and northwestern rainforests (Raxworthy et al. 1998. Fieldiana Zool., n.s. 90:79–92). In some individuals captured for photographs or museum specimens I noticed a peculiar defensive behavior. As shown in Fig. 1, when touched, the individuals curved the body upwards, and moved the forelegs to cover the head and eyes. At the same time, they emitted a typical release-call and a mossy smell. The observed defensive behavior is intended as a sort of "unken reflex," known for *Bombina variegata* and many other anurans and urodeles (Pough et al. 2001. Herpetology, 2nd Ed. Prentice-Hall, Inc. Upper Saddle River, New Jersey. 612 pp.). Unlike most of these species which usually have an aposematic coloration, *B. albilabris* has a cryptic coloration (Cadle 1995. Zool. J. Linnean Soc. 115:313–345). It is worth noting that the upper parts of the body and head (as well as other body parts) of males during the breeding period are covered by horny spiculae. Males also have a well developed and pointed prepollex, used during scramble competition, as shown not only for *B. albilabris,* but also for the closely related *B. occidentalis* (Andreone et al. *In press.* J. Zool., London). By directing the head and hands towards the predator, the threatened individual effectively defends itself. As far as I know this is the first report of defensive behavior and posture in *Boophis*.

Thanks to H. Randriamahazo and J. E. Randrianirina for the assistance in the field, and to the Malagasy institutions which provided authorization for study.

BOOPHIS LICHENOIDES (NCN). **ACOUSTIC BEHAVIOR.** The Madagascan treefrog *Boophis lichenoides* was described (Vallan et al. 1998. Amphibia-Reptilia 19:357–368) from specimens from An'Ala Forest (next to Andasibe, Toamasina Province), Tsararano (Antsiranana Province), and Vevembe Forest (next to Vondrozo, Fianarantsoa Province). This species is peculiar in having extended dermal fringes and a cryptic coloration. In the original description no information was provided about the breeding biology nor vocalizations of this species. Although vocalizations were recorded at Tsararano, they were not described, as they were emitted by a "low motivated" male (i.e., a male that is not particularly sexually active). Recently we found this species at two other sites in NE Madagascar, and recorded the advertisement call, which we describe herein. The new localities are: 1) Menamalona Forest, Masoala Peninsula, Antalaha Fivondronana, Province d'Antsiranana, 15°22.87'S, 49°59.27'E 780 m (voucher specimens Museo Regionale di Scienze Naturali [MRSN] A2047–2052, leg. F. Andreone, 13–18.XII.1999), and 2) next to Manantenina River, Parc National de Marojejy, Andapa Fivondronana, Province d'Antsiranana, 14°26.2'S, 49°46.5'E, 450 m (voucher MRSN A2053 leg. J.E. Randrianirina, July 2000) (vouchers and localities confirmed by M. Vences, Cologne, and Konstanz). At Menamalona several specimens were found along a forest river around a small stagnant pool of about 3 m diameter. This observation confirms the assumption that *B. lichenoides* belongs to the *B. tephraeomystax* group and breeds in temporary ponds. The water at this site was ca. 1 m deep, clear, and 18°C. Other amphibians

FIG. 1. *Boophis lichenoides*, calling specimen photographed at Menamalona Forest (Masoala Peninsula).

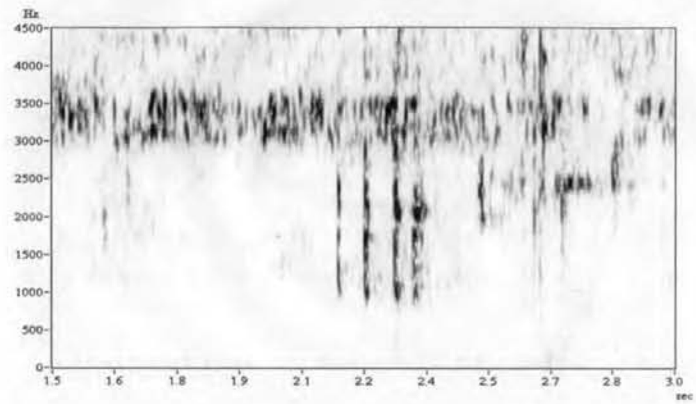

FIG. 2. Sonogram of the advertisement call in *Boophis lichenoides* at Menamalona Forest (Masoala Peninsula), as shown in Fig. 1. Recording temperature = 19°C.

observed at this site were *Mantidactylus tornieri, M. grandisonae*, and *Paradoxophyla palmata*. *Boophis lichenoides* was found on small shrubs around the pool (about 1.5–2.5 m above the ground) and in the water. Some males moved at the surface of the water or stayed hidden under roots of emergent vegetation. During this observation the males on shrubs did not move, although they emitted a croaking vocalization every 1–3 minutes. Males in the water emitted the vocalizations more frequently (each 30–60 sec.), but I did not notice a tendency to initiate a synchronous chorus. The vocalizations emitted from aquatic males consisted of croaking calls composed of several single notes (3 to 6), which corresponded to the rapid inflation of the single subgular vocal sac. The emissions were recorded with a portable Sony and analyzed with the software Voxys 5.1. Duration was 0.22 ± 0.09 sec ($N = 17$; range 0.11–0.43 sec), and frequency ranged from about 800–2500 Hz, with an extension in some cases to about 4000 Hz. The maximum emission peak was around 1000–1200 Hz. A harmonic structure was not clearly visible, although sometimes the presence of two harmonics can be detected, at around 1200 and 2400 Hz. The duration of each single sound was of 0.02 ± 0.009 sec ($N = 66$; range: 0.01–0.05 sec), while intervals between single sounds were 0.05 $\pm$ 0.03 sec ($N = 50$; range 0.005–0.13 sec). Aquatic males emitted the vocalization from the water surface. In this sense, the low fre-

quency of emission of this species is useful in an aquatic medium. At Menamalona we also observed and collected several small tadpoles (MRSN A2052) with a black and yellow banded coloration, similar to that illustrated in Vallan et al. (*op. cit.*), therefore supporting the identification *B. lichenoides*.

Submitted by **FRANCO ANDREONE,** Sezione di Zoologia, Museo Regionale di Scienze Naturali, Via Giolitti, 36, I-10123 Torino, Italy; e-mail: frand@tin.it.

BUFO CALIFORNICUS (Arroyo Toad) **PREDATION**. Herein we report on predation of arroyo toads, observed during the course of a radio-tracking study (Griffin and Case 2001. J. Wildl. Mgmt. 65:633–644) and population surveys in the San Mateo River watershed on U.S. Marine Corps Base Camp Pendleton, San Diego County, California, USA.

Bullfrogs, *Rana catesbiana*, predate other bufonid species (Stuart 1995. Herpetol. Rev. 26:33), including the arroyo toad (Sweet 1993. Second Report on the Biology and Status of the Arroyo Toad (*Bufo microscaphus californicus*) on the Los Padres National Forest of Southern California. Report to USDA Forest Service, Los Padres Natl. Forest). Control of the bullfrog is a priority in the recovery of the arroyo toad (U.S. Fish Wildl. Serv. 1998. Draft Recovery Plan for the Arroyo Toad. Portland, Oregon). During a streamside survey on 24 March 1998, we captured an adult bullfrog, ca. 145 mm SVL. Its stomach contents included three partially digested adult arroyo toads, 57, 44, and 44 mm SVL, now in the Los Angeles County Museum of Natural History (LACM 145293–95). During a streamside survey on 19 May 1998 we captured an adult bullfrog, ca. 140 mm SVL, with stomach contents including one partially digested adult arroyo toad, 58 mm SVL (LACM 145292). On 28 June 1998 we located the radio-transmitter and partially digested body of one adult male arroyo toad, 53 mm SVL (LACM 145296) in the stomach contents of an adult bullfrog, 135 mm SVL (LACM 145297).

On 9 June 1998, we located the transmitter from an adult male arroyo toad in the intestine of an adult two-striped garter snake, *Thamnophis hammondii*, 500 mm SVL (LACM 145298). The toad had been fully digested. On 18 August 1998, we located the transmitter and mostly-digested remains of an adult male arroyo toad in the intestine of another two-striped garter snake, 820 mm SVL (LACM 145299).

On 20 April 1998, one radio-tagged adult female arroyo toad, 58 mm SVL (LACM 145301), was found injured in a dense patch of castor bean plant, *Ricinis communis*. Beak punctures and a severed limb caused by an unidentified avian predator caused the toad's subsequent death. Signs of digging by a bird were also evident at the square meter of sand where the toad had habitually burrowed in the previous 30 days. On 8 July 1998, one radio-tagged female arroyo toad, 63 mm SVL (LACM 145303), was run over and killed by a mountain bicycle on a dirt path by the San Mateo State Park campground.

It appears that males risk predation by aquatic predators during their activities near the stream channel. Effective bullfrog control measures could reduce this risk. We speculate that mortality due to semi-aquatic predators may be less common for females, who spend more time in terrace and upland habitats.

Our thanks to the California Department of Transportation for funding, and to Ed Ervin and Dan Holland for assistance in the field. U.S. Fish and Wildlife Service, California Department of Fish and Game, and U.S. Marine Corps Base Camp Pendleton permitted the study.

Submitted by **PAUL C. GRIFFIN**, University of Montana Wildlife Biology Program, Missoula, Montana 59812, USA, and **TED J. CASE**, Department of Biology, University of California San Diego, La Jolla, California 92093-0116, USA.

BUFO MAZATLANENSIS (Sinaloa Toad), ***RANA TARAHUMARAE*** (Tarahumara Frog). **ECTOPARASITES.** *Bufo mazatlaensis* is known from the Mexican states of Chihuahua, Colima, Durango, Jalisco, Nayarit, Sinaloa, and Sonora (Flores Villela and Gerez 1994. Biodiversidad y Conservación en México: Vertebrados, Vegetación y uso del Suelo, Comision Nacional para el Conocimiento y uso de la Diversidad y Universidad Nacional Autonoma de Mexico, Ciudad Universitaria, México, D.F. 439 pp). *Rana tarahumarae* ranges from southern Arizona to Sinaloa, Mexico (Stebbins 1985. A Field Guide to Western Reptiles and Amphibians, Houghton Mifflin, Boston, Massachusetts. 336 pp.). There are, to our knowledge, no reports of ectoparasites on *Bufo mazatlanensis;* however, the chigger *Hannemania anurae* has been reported from *Rana tarahumarae* by Welbourn and Loomis (1970. Bull. South. California Acad. Sci. 69:65–73). The purpose of this note is to report new host records for chiggers (larval trombiculid mites) from *B. mazatlanensis* and *R. tarahumarae*.

Twenty *Bufo mazatlanensis* (mean SVL 62 mm ± 7 SD, range = 50–80 mm) collected in 1966 from Sonora, Mexico (ASU 6109, 6111–6113, 6115–6117, 6119–6121, 6123, 6126, 6128–6134, 6194) and 42 *Rana tarahumarae* SVL 71 mm ± 16 SD, range 47–99 mm) collected 1969–1989 from Sonora, Mexico (UAZ 31367, 38708, 38710–38712, 39265, 39266, 40016, 40019, 40116, 44146, 44884, 44885, 44888, 44891, 45185, 45187, 45190–45192, 45194, 45926, 45931, 45932, 45936, 45937, 45942–45944, 45947, 45948, 45952, 46086–46089, 47001–47004, 47065, 50706) were examined for ectoparasites. These specimens were preserved in formalin and stored in alcohol. The body surface was searched for ectoparasites under a dissecting microscope. Ectoparasites (all chiggers) were removed with forceps, placed in a vial of 70% ethanol and shipped to WJW for study where they were mounted in PVA-LP (polyvinyl alcohol-lactophenol) and identified. Voucher slides were deposited in the United States National Chigger Collection, housed at Chaminade University, Honolulu, Hawaii. Fourteen *R. tarahumarae* were infested with *Hannemania monticola* (mean 5 ± 2 SD, range 4–8), 4 *B. mazatlanensis* were infested with *H. bufonis* (mean 2 ± 1 SD, range 1–4), and 14 *B. mazatlanensis* were infested with *H. hylae* (mean 5 ± 4 SD, range 1–12). Two *B. mazatlanensis* had concurrent infestations with *H. bufonis* and *H. hylae*.

Hannemania bufonis was described from *Bufo punctatus* collected in Riverside County, California (Loomis and Welbourn 1969. Bull. South. California Acad. Sci. 68:161–169). *Hannemania hylae* was redescribed from *Hyla cadaverina* collected in San Diego County, California but is also known to infest *Hyla arenicolor* from Arizona, west Texas, southern Utah, and northern Sonora, Mexico and *Hyla cadaverina* from Baja California, Mexico (Loomis and Welbourn, *op. cit.*). *Bufo mazatlanensis* is a new host

record for both *Hannemania bufonis* and *H. hylae;* Sonora, Mexico is a new locality record for *H. bufonis. Hannemania monticola* was originally described from *Hyla eximia* collected in Durango, Mexico but has been reported to infest the salamander *Ambystoma rosaceum* and the frog *Eleutherodactylus* (= *Tomodactylus*) *saxatilis* (Welbourn and Loomis, *op. cit*). *Rana tarahumarae* is a new host record for *Hannemania monticola;* Sonora is a new locality record.

We thank Michael E. Douglas (formerly of Arizona State University) for permission to examine *B. mazatlanensis* and Charles H. Lowe (University of Arizona) for permission to examine *R. tarahumarae*.

BURSEY,** Pennsylvania State University, Shenango Campus, Department of Biology, Sharon, Pennsylvania 16146, USA.

BUFO TALADAI (NCN). **DIET.** The feeding habits of most Cuban toads (*Bufo* spp.) have not been previously investigated. In this paper, the first data on the diet of *Bufo taladai* are reported.

An adult female (103.9 mm SVL) *Bufo taladai* was collected in Altiplanicie de El Toldo, Alturas de Moa, Holguín province, Cuba on 16 September 1998. The specimen was maintained in a cage for some days, during which time three fecal balls were obtained. The specimen has been deposited in the herpetological collection of BIOECO at Santiago de Cuba (BSC.H 1976).

From the feces, we identified eight food items representing three classes and eight orders. In addition, grit and plant material were found, although ingestion of these materials was likely incidental. Further, we could identify three items as *Solenopsis* sp. (Formicidae), *Cynorta* sp. (Opiliones) and *Centruroides anchorellus* (Scorpiones). Ants and mites were present in the greatest numbers, followed by the orthopterans. Types and number of food items are presented in Table 1.

The relatively wide variety of food found in only three fecal balls suggests that *B. taladai* is a dietary generalist. This agrees with the results reported by Sampedro et al. (1982. Poeyana 233:1-14) for *B. peltacephalus* from Cuba and by Parsons (1995. Herpetol. Rev. 26:202) for *B. guentheri* from Hispaniola.

TABLE 1. Types and number of food items recovered from three fecal balls of *Bufo taladai* from Altiplanicie de El Toldo, Holguín province, Cuba.

Food item	Number
Arachnida, Acarina	16

DENDROPHRYNISCUS MINUTUS (Amazon Toadlet). **DEFENSIVE BEHAVIOR.** *Dendrophryniscus minutus* is a small bufonid that occurs in Amazonian Peru, Ecuador, Colombia, Brazil, southern Guyana, and French Guiana. This species possesses a brown dorsum and a bright orange venter. The palms and soles are either orange or red (Rodríguez and Duellman 1994. Guide to the Frogs of the Iquitos Region, Amazonian Peru. Nat. Hist. Mus. Univ. Kansas. 80 pp.). On 17 February 2001, a male *D. minutus* (SVL 16.3 mm) was collected in primary rainforest (Peru: Loreto: Lower Río Samiria, Pacaya/Samiria National Reserve). As I attempted to take photographs prior to release, this specimen consistently flipped over on its back leaving itself in dorsal recumbency with its legs held upward. While in this position, the frog remained motionless. This behavior exposed the bright orange patch on the venter and the orange palms and soles. It also appeared that the animal may have been feigning death. This behavior was repeated five times.

A behavior similar to the one described above has been reported for the Darwin's frog (*Rhinoderma darwini*) (Pough et al. 2001. Herpetology 2nd Ed. Prentice Hall, New Jersey. 612 pp). I am not aware of any published records of this behavior for *D. minutus*, however, this behavior has been observed in the field by others (W. W. Lamar, pers. comm.).

LEPTODACTYLUS KNUDSENI (Knudsen's Bullfrog). **PREDATION**. During May 1999, at the field station of the Nouragues (4°5'N, 52°41'W, 110 m elev.), 8 km N of Saut Pararé, Arataye River, French Guiana, one of us (RB) observed an adult giant tarantula *Theraphosa leblondi* (Theraphosidae) preying on a *Leptodactylus knudseni* (ca. 90 mm SVL) during a rain at dusk. The tarantula was maintaining the freshly dead frog with its chelicera, on the ground along a stream. When disturbed, the tarantula escaped underwater with the frog. This frog could not be found again, but there is a voucher specimen from the same population and locality deposited at the Museum National d'Histoire Naturelle, Paris (MNHN 1999.4934, collected by Jean-Pierre Gasc). In the same locality and month, *T. leblondi* was reported to prey on the caecilian *Oscaecilia zweifeli* (Boistel and Pauwels 2002. Herpetol. Rev. 33:120–121).

We thank J.-C. Baloup, F. Catzeflis, P. Charles-Dominique, M. Dewynter, P. Gaucher, G. Lenglet, and S. Lochon for working facilities.

MANTELLA NIGRICANS (NCN). **NOCTURNAL ACTIVITY.** The Malagasy poison frogs of the genus *Mantella* are considered diurnal species. This is corroborated by their aposematic bright coloration, a character which is usually correlated with diurnal activity (Vences et al. 1999. Alytes 17[1–2]:3–72). To my knowledge there are no records of nocturnal activity for any of the 17 species of this genus. Here I report nocturnal activity in *M. nigricans* in NE Madagascar, Masoala Peninsula, Menamalona Site (Antalaha Fivondronana, Antsiranana Faritany, 15°22.87'S, 49°59.27'E, 780 m elev.). Menamalona is also a new site for the species' distribution. Species determination and locality were verified by M. Vences. On 15 December 1999 at 1930 h (ca. one hour after sunset), while searching for other amphibians following standard methods (opportunistic searching and bioacoustic identification), I heard chirping and metallic notes emitted by frogs at ground level. I recorded these calls for several minutes. I then spotlighted the calling frogs—two male *M. nigricans* engaged in territorial/sexual interactions. Vocalizations in this species (as in other *Mantella* spp.) are usually emitted during the daytime when temperatures are sufficiently high. The nocturnal vocalization reported herein may be explained by the high sexual motivation of the frogs (they were likely at the peak of their breeding activity) and the high air temperature (23°C).

The specimens are catalogued in the herpetological collection of Museo Regionale di Scienze Naturali, Torino, Italy (temporary numbers: MRSN-FAZC 10399-10400). Thanks to J. E. Randrianirina for help in the field, and to the Wildlife Conservation Society for logistical assistance.

RANA AURORA DRAYTONII (California Red-Legged Frog) **PREDATION**. Predation on the federally threatened *Rana aurora draytonii* tadpoles and metamorphs by the introduced bullfrog (*Rana catesbeiana*) has been documented (Cook and Jennings 2001. Herpetol. Rev. 32:182–183). Here, I expand on the life stages of California red-legged frog taken by bullfrogs.

On 16 March, 2001 at Ledson Marsh, Annadel State Park, Sonoma County, California an adult female bullfrog (195 mm SUL, 805 g [including stomach contents], and 71 mm gape) was observed at a known California red-legged frog breeding site. The bullfrog was lethargic and was easily captured. Inspection of its stomach contents produced an adult male California red-legged frog (95 mm SUL, 85 g) with partially digested legs. The bullfrog and prey are catalogued at the California Academy of Sciences; CAS 221058 (*R. catesbeiana*) and CAS 221059 (*R. a. draytonii*).

This predation observation indicates that bullfrogs are capable of taking adult-sized California red-legged frogs. The predator bullfrog was a large individual, although not the largest observed at the marsh. The average SULs of adult bullfrogs at this locality are 167.2 ± 10.3 mm (N = 17 males) and 162.071 ± 31.3 mm (N = 14 females). The ingested *Rana aurora draytonii* was of average size for males. The average SULs at this locality are 99.4 ± 10.4 mm (N = 72 males) and 108.0 ± 14.3 mm (N = 73 females).

Predation on adult *R. a. draytonii* can have a disproportionate effect on a population compared to the predation on younger life stages. The California red-legged frog has an r-strategy approach to reproduction, including production of many offspring; low survival rate at the egg, tadpole, and metamorphic life stages; and few frogs reaching sexual maturity. Therefore, resource managers should be aware that the loss of a few breeding adults could significantly decrease reproductive output and frog numbers in a local population. Also, adult males are likely to be more vulnerable to predation during breeding periods because of their increased activity and congregation at breeding choruses.

My thanks to Philip T. Northen for reviewing the manuscript. Permission to handle and collect specimens was granted under U.S. Fish and Wildlife Service and California Department of Fish and Game permits.

TESTUDINES

GOPHERUS POLYPHEMUS (Gopher Tortoise). **NEONATE DIET**. Although a variety of food items (principally foliage, but also including insects, carrion, rocks, charcoal, and bone material) are reported to be consumed by adult and young gopher tortoises (Garner and Landers 1981. Proc. Conf. Southeast Assoc. Fish and Wildl. Agencies 35:120–134; Macdonald and Muschinsky 1988. Herpetelogica 44:345–353; Jackson and Ostertag 1999. Herpetol. Rev. 30:40), little is known about the dietary requirements of neonates. On 30 August 2000 a neonate gopher tortoise was found on the apron of an active adult gopher tortoise burrow on the Wade

Tract Preserve, Thomas Co., Georgia, USA (30°45'N, 84°00'W), a privately-owned quail plantation under a conservation easement managed by Tall Timbers Research Station. The preserve contains old-growth longleaf pine forest with a mixed shrub oak and wiregrass understory that is maintained using biennial prescribed fires. The neonate tortoise was in a small depression underneath a large Tomahawk™ trap placed at the entrance of the burrow in order to trap the resident adult tortoise. We noticed that the neonate had fibrous root tissue hanging from its mouth and that within the depression small exposed roots were visible. The neonate was of a size that indicates it had recently emerged from a nest (48 mm CL, 50 mm PL, 34 g) (Cox et al. 1987. Florida Game and Freshwater Fish Commission: Nongame Wildlife Program Technical Report No. 4). The animal was brought to the lab, then marked and released at the same location the subsequent evening. Upon release, the neonate walked < 1 m to an area of exposed roots on the burrow apron and proceeded to unearth and eat the roots. This took place for ca. 15 min. before the neonate walked into the adult burrow and disappeared from view.

A prescribed burn was conducted a week prior (24 August 2000) in the area surrounding the tortoise burrow and the only vegetation available of an appropriate height for the neonate was resprouts of wiregrass *(Aristida stricta* Michx.). We believe the neonate was eating roots because of the scarcity of green foliage available following the burn and that fibrous roots may provide a temporary nutrient source for neonate tortoises during periods of low food availability.

MACROCLEMYS TEMMINCKII (Alligator Snapping Turtle). **AERIAL BASKING**. *Macroclemys temminckii* is a highly aquatic turtle that rarely leaves the water except to nest (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Institution Press, Washington and London. 578 pp.). In fact, we are aware of only one previously published observation (Ewert 1976. Herpetologica 32:150-156) of aerial basking by this species.

On 24 August 1998 one of us (JAS) captured a recent hatchling (yolk scar and egg tooth evident) in a basking trap placed under an emergent snag in the Chickasawhay River, Greene Co., Mississippi, USA. The turtle had a carapace length of 4.2 cm and weighed 19 g. Although the turtle was not seen aerially basking, it is highly unlikely that it could have entered the trap without falling from the above snag. Although the egg tooth was still present indicating recent hatching, the turtle's carapace and head were covered with a thick coat of algae, which it may have been attempting to reduce by basking.

LACERTILIA

ANOLIS HOMOLECHIS HOMOLECHIS (NCN). **THERMAL BIOLOGY AND MICROHABITAT**. Mean body (29.4–33.8°C) and air temperatures (27.9–32.1°C) have been reported for *Anolis homolechis* at several places in Cuba (Rodríguez Schettino 1999. *In* L Rodríguez Schettino [ed.], The Iguanid Lizards of Cuba, pp. 104–380. University Press of Florida, Gainesville). Previous reports are from several forest types, but do not include microphyllous semi-deciduous forest on limestone. Here, we report dry-season observations of *A. homolechis* from such a forest at El Cenote, 16 km SSE of Playa Larga, Península de Zapata (Zapata Swamp), Matanzas Province, Cuba.

On 9 April 1994 between 0900 and 1130 h, we collected data on 10 males and two females. Lizard body temperatures (T_B) and air temperatures (T_A) at the capture site were obtained with a Schultheis rapid-reading cloacal thermometer. One lizard that was moving when first seen was excluded from the analysis. After taking each body temperature, lizards were released at their place of capture. We also recorded microhabitat data on perch site, orientation, and insolation category.

Both females had a T_A of 31.0°C, and a T_B of 32.0°C. Mean T_B of males (30.6°C; range: 28.0–33.4°C) was higher than their mean T_A (29.9°C; range: 28.0–32.8°C). Air and body temperatures were highly correlated ($r = 0.92$; $p < 0.01$) and increased during the course of the morning from 28.0°C (T_A and T_B) at 0920 h to 32.8°C (T_A) and 33.4°C (T_B) at 1130 h.

Except for one male on the ground, all males were on tree trunks, heads oriented down; mean perch height for males was 0.36 m (range: 0.2–0.5 m; CV = 28.5). Both females were 0.20 m above the ground, also head downwards. Males were as often in the shade as in filtered sun; both females were in filtered sun.

Based on our data, the thermal biology of *A. homolechis* in a microphyllous semi-deciduous forest on limestone during the dry season at Zapata Swamp is similar to that reported by Ruibal (1961. Evolution 15:98–111) during the wet season (T_B = 31.8°C; T_A = 30.5°C) for a population in a broadleaf semi-deciduous forest on limestone located 15 km SW of Camagüey (city). Also, microhabitat use, assessed as position on the tree and body orientation, is similar. However, the mean perch height reported here is less than values reported previously (see summary in Rodríguez Schettino, *op. cit.*), probably because the trees of the forest at El Cenote have thin trunks, are not tall, and are scattered, which provides a homogeneous, structurally low habitat for *A. homolechis*. Our findings suggest that *A. homolechis* maintains a body temperature slightly higher than air temperature during both wet and dry seasons, and that between-site differences in perch height may depend on vegetation structure.

We thank Ramona Oviedo (Institute of Ecology and Systematics, La Habana) for characterizing the forest type.

Submitted by **LOURDES RODRÍGUEZ SCHETTINO**, Departamento de Vertebrados, Instituto de Ecología y Sistemática, C. de Varona km 3.5, Boyeros, CP 10800, AP 8029, La Habana, Cuba (e-mail: zoologia.ies@ama.cu), and **KEVIN DE QUEIROZ**, Division of Amphibians and Reptiles, National Museum of Natural History, Smithsonian Institution, Washington, DC 20560-0162, USA (e-mail: dequeiroz.kevin@nmnh.si.edu).

ANOLIS SAGREI SAGREI (Cuban Brown Lizard; Chino; Torito). **HABITAT USE AND THERMAL BIOLOGY**. *Anolis sagrei sagrei* is the most common lizard in Cuba, living in almost all vegetation zones, including many habitats modified by humans (Rodríguez Schettino 1999. *In* L. Rodríguez Schettino [ed.], The Iguanid Lizards of Cuba, pp. 104–380. University Press of Florida, Gainesville). Nevertheless, few data address the vegetation types that it uses and its thermal biology. Berovides Alvarez and Sampedro Marín (1980. Cien. Biol. 5:115–122) found this species in a secondary semi-deciduous forest at Tapaste, La Habana Province, Cuba, and Garrido (1980. Peyana 203:1–19) in grasslands and pastures at Península de Zapata (Zapata Swamp), Matanzas Province, Cuba. Ruibal (1961. Evolution 15:98–115) obtained a mean body temperature of 33.1°C and mean air temperatures of 30.7°C in the morning and 33.1°C in the afternoon, during the wet season for a population at Santa Teresa, 9 km W of Camagüey (city). Hence, we report thermal and habitat data on male *Anolis s. sagrei* from a dry swamp forest habitat partly cleared by beekeepers 3 km N of Pálpite, Zapata Swamp.

Data were collected on 8 April (dry season) 1994 between 1500 and 1630 h. Body temperatures (T_B) of active lizards and air temperatures (T_A) at the location of each initial sighting were obtained with a Schultheis rapid-reading cloacal thermometer. We also recorded substrate type and insolation category. Lizards moving when first seen (N = 3) were excluded from the analysis. We collected data for 10 adult males, all first seen on tree trunks situated at the edges of forest clearings. Mean perch diameter was 0.22 m (range: 0.08–0.50 m; coefficient of variation [CV] = 68.3%); mean perch height was 0.57 m (range: 0.2–1.2 m; CV = 64.6%). Seven anoles were oriented head down; three head up.

Although several authors have stated that *A. s. sagrei* perches near the ground, only Llanes Echevarría (1978. University Student Report, University of Havana) and Sampedro et al. (1982. Cien. Biol. 7:87:103) have reported quantitative data on perch height and diameter: Mean height 0.7 m, mean diameter 0.03 m (Llanes Echevarría, *op. cit.*); mean height 0.61 m, mean diameter 0.08 m (Sampedro et al., *op. cit.*). Both of these studies were for populations in semi-deciduous forests. Our values for perch height are lower and for perch diameter higher in a different type of vegetation, suggesting that perch height and diameter of male *Anolis s. sagrei* varies with local vegetation structure.

Mean T_B of males (32.1°C; range: 31.0–34.0°C; N = 7) averaged slightly higher than mean T_A (31.0°C; range: 30.0–32.0°C; N = 7). These values are lower than those obtained by Ruibal (1961, *op. cit.*; T_B = 33.9°C; T_A = 33.1°C), also collected in the afternoon, which may reflect the lower temperatures prevailing in the dry season.

Six of the ten males were in shaded places; the other four were in filtered sun. Ruibal (*op. cit.*) stated that *A. sagrei* is a sun-dwelling species and Rodríguez Schettino (*op. cit.*) noted that it frequently basks in open places, so the observed pattern may reflect the predominance of shade in the study area and/or that lizards sheltering in shade had already achieved their preferred T_B.

We thank Ramona Oviedo (Institute of Ecology and Systematics, La Habana) for characterizing the forest type.

Submitted by **LOURDES RODRÍGUEZ SCHETTINO**, Departamento de Vertebrados, Instituto de Ecología y Sistemática, C. de Varona km 3.5, Boyeros, CP 10800, AP 8029, La Habana, Cuba (e-mail: zoologia.ies@ama.cu), and **KEVIN DE QUEIROZ**, Division of Amphibians and Reptiles, National Museum of Natural History, Smithsonian Institution, Washington, DC 20560-0162, USA (e-mail: dequeiroz.kevin@nmnh.si.edu).

CROTAPHYTUS COLLARIS (Eastern Collared Lizard). **CAUDOPHAGY.** *Crotaphytus collaris* is a known predator on a variety of lizard taxa (Best and Pfaffenberger 1987. Southwest. Nat. 32:415–426; Lappin 1999. Unpubl. PhD Dissertation. Univ. California, Berkeley; McAllister 1985. Southwest. Nat. 27:358–359). This species also is known to attempt predation on animals larger than itself (Strasser 1931. Bull. Antivenin Inst. America 5:41). Here, I report an unusual instance of predation by a *C. collaris* from Arizona (USA), which, together with information from laboratory feeding experiments, suggests that prey lizard morphology may influence the incidence of caudophagy. Specifically, the evidence supports the hypothesis that caudophagy is more likely to occur when the prey lizard possesses anti-predator integumentary modifications, such as the cycloid scales and osteoderms of skinks.

At 0515 h on 3 May 1996, I encountered an adult (102 mm SVL) male *C. collaris* on a large granite boulder along Boriana Mine Rd. ca. 1 mi N of Wabayuma Peak turnoff going to Prescott, Yavapai Co. The lizard was bleeding from the right corner of mouth and four spots on top of the head, giving the appearance of pinpricks. Subsequent stomach-flushing revealed that the *C. collaris* had recently eaten the tail from a large skink. The tail section consumed was the original (i.e., unregenerated) and measured 92.5 mm. The locality and comparison of the tail with those of museum specimens revealed it to belong to a *Eumeces gilberti*. Further, its size and lack of ventral juvenile coloration suggest that the *Eumeces* to which it belonged was an adult, possibly comparable in size to the *C. collaris*. The injuries to the *C. collaris* appear to have been incurred during the interaction with the *Eumeces*.

Skinks are more likely than other potential lizard prey taxa to be subjected to caudophagy rather than complete consumption by *C. collaris*. During five captive feeding trials I conducted among three individual adult *C. collaris*, caudophagy alone occurred every time a *Eumeces* sp. was the prey item, whereas caudophagy alone occurred in < 4% of trials with other prey lizard taxa (e.g., *Uta*, *Cnemidophorus*) [caudophagy in 2 of 57 trials among 25 *C. collaris* individuals]. During feeding trials with *Eumeces* sp. as the prey item, the *C. collaris* would chase the skink, repeatedly attempt to close its mouth on its body, and inevitably have the skink slip out of its jaws. Usually after multiple attempts to grab the skink by the body, the *C. collaris* would inevitably bite the tail, which was then autotomized and eaten.

Squamates that are skink-eating specialists possess modifications of the trophic apparatus that are proposed to aid in gripping the hard and slippery integument of skinks, such as hinged teeth in *Lialis* (Patchell and Shine 1986. J. Zool. Lond. 208:269–275) and snakes (Savitzky 1981. Science 212:346–349) and a unique intramaxillary joint in *Casarea* (Frazzetta 1970. Am. Nat. 104:55–72; Cundall and Irish 1989. J. Zool. Lond. 217:189–207). Observations herein support the view that integumentary specializations of skinks are effective anti-predator modifications,

at least when the predator does not possess a specialized trophic apparatus to cope with the modifications.

Specimens were handled and collected under Arizona Game and Fish Scientific Collecting Permit SP657703 issued 8 April 1996 to A. K. Lappin.

CYCLURA CYCHLURA INORNATA (Allen Cays Rock Iguana). **BIRD PREDATION.** Although iguanas are generally considered to be herbivorous (e.g., Pough et al., 2001. Herpetology. Prentice Hall. New Jersey. 577 pp.), some members of the genus *Cyclura* are known to supplement their diet with vertebrate carrion (Iverson 1979. Bull. Florida State Mus., Biol. Sci. 24:175–358.; Glenn et al., *in press*). Based on these observations, it has been suggested that potentially all members of this genus are opportunistic scavengers of vertebrate carcasses (Glenn et al., *op. cit.*). We augment recent observations with data from the Allen Cays, northern Exuma Islands, Bahamas indicating that *C. cychlura inornata* can also prey on nestling birds.

Occasional bird consumption by *C. c. inornata* was first suspected when carcasses of Audubon's Shearwaters (*Puffinus lherminieri*) with missing breasts and heads were periodically found in substantial numbers on both Allen and U Cays (mummified carcasses of at least a dozen now archived with Sandra Buckner, Past President of the Bahamas National Trust). During the summer of 2001, at least 100 such carcasses were discovered on Allen Cay, where a large population of Audubon's Shearwaters resides (Carey et al. 2001. Protected Areas Management Strategy for Bahamian Terrestrial Vertebrates: Iguanas and Seabirds. IUCN/SSC Conservation Breeding Specialist Group, Apple Valley, Minnesota). A small population of *C. c. inornata* (at least 11 individuals) was confirmed on this same cay. Rock iguanas on this cay are larger than those on either Leaf or U Cay. Of six captured on Allen Cay, four were males (56.5–62.0 cm SVL), and two were females (51.0–53.0 cm SVL). The largest iguanas recorded on the other islands over 21 years of fieldwork were a male at 48.7 cm SVL and a female at 39.5 cm SVL (Hines, Iverson, and Valiulis, unpubl. data). While this difference in size may be attributable to differences in available food plants (e.g., presence of morning glories, *Ipomea pes-caprae*) or reduced competition due to the low population size, bird consumption may contribute to these differences.

Direct evidence of iguana predation was recorded on 13 May 2001 at 1530 h on U Cay, when an adult female iguana (31.9 cm SVL) was observed (B. Dunham, S. Young, pers. comm.) shaking a shearwater nestling by the head, which it eventually bit off. The iguana immediately took cover in a nearby burrow, but a shearwater nest was discovered within 1 m of the burrow, suggesting that the iguana had taken the hatchling from its nest. Fresh blood around the iguana's mouth, and the fresh, decapitated carcass of the shearwater nestling support the notion of predation.

Another possible predation incident was recorded on Leaf Cay on 1 July 2001, when a nestling white-crowned pigeon (*Columba leucocephala*) disappeared from its nest 120 cm up in a silver thatch palm (*Coccothrinax argentata*). The nest was covered in blood, and the legs of the nestling were found on the ground ~2 m away. The nest appeared to have been visited by a terrestrial predator as one side of it was crushed, and a high local canopy density would have limited access by a raptorial bird. Rock iguanas are often found in trees (Iverson 1979, *op. cit.*) and are the largest terrestrial organism on this mammal-free island, making them a prime suspect in this second predation incident.

Besides the aforementioned incidents, vigorous nest defense by *Mimus gundlachii* (Bahamas Mockingbird) against *C. c. inornata* implies that iguana predation on nestlings may be frequent. On 15 June 2001, we found an active *M. gundlachii* nest (three eggs) 107 cm up in a wild saffron tree (*Bumelia americana*) on the southeast corner of Leaf Cay. Nest development and parental behavior were observed from 15 June to 11 July 2001, when the young fledged. Once the eggs hatched, we observed aggressive encounters between the mockingbirds and several *C. c. inornata*. When iguanas approached the area below the nest, one parent would dive and peck at the iguana's tail from the ground or from a nearby branch or stump. If one parent was insufficient to deter the iguana, both birds would attack by alternately diving at and pecking at the tail. The iguana would respond by slapping its tail at the attacker and trying to deflect the attacks (Quicktime™ movie clip [14.5 MB] of mockingbird aggressive behavior toward iguanas available from JBI [johni@earlham.edu]). In all cases the birds persisted until the iguana had retreated to a distance of at least 3 m from the nest.

Evidence suggesting that rock iguanas hunt adult birds is lacking, but our observations indicate that *C. c. inornata* may opportunistically prey on poorly mobile chicks. The relative importance of predation on hatchling birds in the diet of *C. c. inornata*, which is likely both habitat- and circumstance-specific, remains unclear.

ELGARIA KINGII NOBILIS (Arizona Alligator Lizard). **MAXIMUM SIZE.** Based on measurement of > 400 *Elgaria kingii* from throughout Arizona (USA), Bowker (1994. Herpetol. Rev. 25:121) reported a maximum size for the species to be 133 mm SVL, a male from Camp Geronimo Boy Scout Preserve, 6 mi E Pine, Gila County. Here, we report on a larger individual from Greenlee County, Arizona.

On 9 September 2000 at 1745 h, we captured a large male *Elgaria kingii nobilis* with an incomplete tail moving among piled rocks in juniper-oak woodland at the bottom of Dry Prong Canyon, Blue Range, Greenlee County, Arizona (33°17'41"N, 109°07'00"W), USA. This male measures 140 mm SVL. Andrew T. Holycross verified its size. We deposited the specimen in the Arizona State University Herpetology Collection (ASU 33047) and was collected under license No. HL101541 from the Arizona Game and Fish Department issued to TCB.

Submitted by **THOMAS C. BRENNAN**, 13201 South Wakial Loop, Apt. 2139, Phoenix, Arizona 85044, USA (e-mail: mail@brennanart.com), and **MARTIN J. FELDNER**, 1918 East Redfield Road, Tempe, Arizona 85283, USA.

EUMECES FASCIATUS (Five-lined Skink). **DIET**. Although the five-lined skink is widely distributed in eastern North America, little information on its diet has been published. Several accounts published before the mid-1950s (Fitch 1954. Univ. Kansas Publ. Mus. Nat. Hist. 8:1–156; and refs. within) suggest that five-lined skinks prey on arthropods but that preference for arachnids (spiders and harvestmen), orthopterans (grasshoppers), and blattids (cockroaches) exists. Little information on the natural diet of *E. fasciatus* in the Canadian portion of its range has been published (but see Judd 1962. Can. Field-Nat. 76:88–89).

As part of a continuing long-term study of *E. fasciatus* at Point Pelee National Park, Leamington, Ontario, Canada (42°10'N, 82°30'W) (Hecnar 1991. M.Sc. thesis, Univ. Windsor, Windsor, Ontario; Hecnar 1994. Can. J. Zool. 72:1510–1516; Hecnar and M'Closkey 1998. Biol. Conserv. 85:213–222), we conducted diet analyses. In late June and early July 2000 we collected 21 scats along an 8 km transect of stabilized dune habitat. We collected intact (with uric acid cap), relatively fresh scats that were spatially segregated to ensure that they represented separate individuals. We measured total scat length (mm) and preserved scats in vials containing 40% ethanol.

To identify food items, we separated scat contents in water using probes under a dissecting microscope. Scats consisted of fragments of the hard chitinous exoskeletons of individual arthropods. Remains of individual prey items tended to occur in succession along the length of each scat. This permitted us to determine the number of items per scat and numerous larger fragments facilitated identification. In most cases, parts of food items were missing, suggesting that skinks battered their prey to subdue it prior to swallowing (Fitch 1954, *op. cit.*).

We found a total of 68 individual food items belonging to 11 taxonomic orders among the 21 scats (Table 1). Over 80% of the items belonged to 4 orders: Araneae (25%), Coleoptera (22%), Opiliones (18%), and Blattaria (18%). Nearly half of the items (43%) were arachnids (aranids + opiliones). Individual scats contained an average of 3.2 ± 0.36 items (range 1–6) but the number of items per scat was not correlated with scat length ($r = 0.31$, $p = 0.17$). In many cases we were able to identify prey to taxonomic levels lower than order. Our most detailed identifications and their incidence (% of scats) included: terrestrial ground snail (*Helix*) shells (14%) (Table 1 [A]), jumping spider (Salticidae) and wolf spider (Lycosidae) (57%) (B), harvestmen (Opiliones) (48%) (C), grasshopper (Acrididae) (10%) (D), cricket (Gyrillidae) (10%) (E), cockroach (43%) (F), leafhopper (10%) (G), antlion (Myrmeleonidae) (5%) (H). Beetle (Order Coleoptera) remains consisted of fragments, entire beetles, or grubs (43%) (I). Most were ground beetles (Carabidae) and several individuals were *Bembidion* sp. Other individual items included a weevil (Family Curculionidae, subfamily Brachyderinae) (5%), carpenter ant (Formicidae: *Camponotus* sp.) (5%) (J), and blue-bottle fly (Calliphoridae) (5 %) (K).

Most of the food items were ca. 1–2 cm long and from mobile ground-dwelling arthropods rather than actively flying forms. However, more sedentary prey items such as ootheca (egg cases) and grubs suggest that skinks also rely on chemosensation for locating prey. These results concur with other studies which suggest skinks are gape-limited predators that locate prey by both visual and chemosensory detection (Fitch 1954, *op. cit.*; Judd 1962, *op. cit.*). Five-lined skinks spend most of their time under cover objects, from which they make short foraging forays (Fitch and von Achen 1977. Herpetologica 33:303–313). Most prey we detected were forms that commonly occur among grasses and herbs in open stabilized dune habitat. Most of the beetles we found were ground beetles (Carabidae) which are known to be primarily nocturnal; however, skinks are diurnal. This observation suggests that Pelee skinks must also feed when they are under cover objects where beetles are commonly found in the daytime as previously reported by Fitch (1954, *op. cit.*). Ants are common in our study area (Hecnar 1991, *op. cit.*) but we only found one carpenter ant in a scat. This relatively large ant is probably greater than the minimum size of

moving prey that will attract attention by a skink. Fitch (1954, *op. cit.*) also found few ants in Kansas five-lined skink diets and noted that those eaten were individuals of large bodied ant species. We did not sample arthropods in the environment to determine the spectrum of potential prey, but arachnid (spiders and harvestmen) remains in the scats were clearly over-represented (43% of items, 71% incidence) in the diet. Arachnids comprised 52% of food items in scats in Kansas (Fitch 1954, *op. cit.*) and 60% of stomach contents in Kentucky skinks (Barbour 1950. Copeia 1950:100–107). Judd (1962, *op. cit.*) examined stomach contents of seven five-lined skinks from Rondeau Provincial Park (58 km E of Point Pelee) and reported a preponderance of crickets, spiders, and cockroaches. Soft-bodied arthropods may be underrepresented in scat analyses because they would be more easily digested than hard-bodied species. However, Fitch (1954, *op. cit.*) reported similar results from both stomach and scat analyses. Our results strongly suggest that five-lined skinks at Point Pelee National Park are arachnid specialists as they appear to be elsewhere in their range (Fitch 1954, *op. cit.*).

We thank Parks Canada, G. Mouland and T. Linke of Point Pelee National Park, NSERC and PREA for their support.

LEIOCEPHALUS CARINATUS VIRESCENS (Exuma Islands Curlytail Lizard). **INTERSPECIFIC AGGRESSION**. Knapp (2001. Herpetol. Rev. 32:104–105) reported two aggressive interactions between a resident adult male curlytail, *Leiocephalus carinatus virescens*, and two Bahamas mockingbirds, *Mimus gundlachii*, that were each preceded by an aggressive encounter between an intruder curlytail and the resident male. Based on his observations, Knapp (2001) suggested that either high hormone levels in the resident curlytail arising from its interaction with intruders may have prompted unusual aggressive responses towards the mockingbirds, or curlytail-mockingbird aggression is routine. We provide observations that support the latter.

On 15 June 2001, we discovered a *M. gundlachii* nest with three eggs at a height of 107 cm in a wild saffron tree (*Bumelia americana*). The tree was located at the edge of a clearing at the southeastern point of Leaf Cay, northern Exuma Islands, Bahamas (24°44'48"N; 76°50'09"W). Development of the nest and parental behavior were observed from 15 June to 11 July 2001 when the young fledged. Mockingbirds on this island generally ignore adult curlytails, but during this time, we observed at least 15 aggressive interactions between the parent mockingbirds and a male curlytail (~10 cm SVL) defending an area below the nest. All but one or two of these encounters occurred in the absence of other nearby curlytails, so no opportunity existed for aggression in the resident curlytail to be intruder-facilitated. Observed interactions were between the resident curlytail and one parent or the other, but only once or twice included both parents. In instances when the mockingbirds were on the ground, the curlytail would generally chase the birds off by lunging at them with an open mouth. At other times, the birds would dive at the curlytail from an elevated position. In these situations, the curlytail would flee from the birds as they attempted to peck its tail. Aggressive encounters between the curlytail and the mockingbirds at least doubled in frequency once the eggs hatched. The extent of these interactions suggests that curlytail-mockingbird aggression is a routine component of their natural history.

LEIOCEPHALUS MACROPUS, LEIOCEPHALUS RAVICEPS, AND LEIOCEPHALUS STICTIGASTER (Curly-Tailed Lizards). **CLUTCH SIZE**. Lizards of the genus *Leiocephalus* occur throughout the Caribbean and the Bahamas (Pregill 1992. Univ. Kansas. Mus. Nat. Hist. Misc. Publ. [84]:1–69). Despite this wide distribution, relatively little is known about reproduction in the genus. Hence, we report observations of clutch size in three species of Cuban *Leiocephalus: L. macropus* and *L. raviceps* primarily from the US Naval Base at Guantanamo Bay, and *L. stictigaster* from Cienfuegos, Granma, Holguin, and Villa Clara based on dissection of specimens from the University of Kansas Museum of Natural History.

Using counts of both follicles and eggs, we found mean clutch size to be 1.75 ± 0.25 (N = 4; range = 1–2) in *L. macropus* and 1.67 ± 0.21 (N = 6; range = 1–2) in *L. raviceps*. The lone female *L. stictigaster* examined contained two enlarged follicles.

Our observations on clutch sizes in these three *Leiocephalus* species agree with previous observations of small clutch sizes between 1 and 2 eggs in the genus. Data exist for three additional species: *L. psammodromus* (Caicos Islands) for which Smith and Iverson (1993. Can. J. Zool. 71:2147–2151) reported a mean clutch size of 1.72 (N = 42), and *L. schreibersii* and *L. semilineatus* (both Dominican Republic) for which Schreiber et al (1993. Florida Sci. 56:82–90) and Nelson et al. (2001. Contemp. Herpetol. [http://dataserver.calacademy.org/herpetology/herpdocs/ch/2001/1/index.htm]) reported clutch sizes, respectively, of one (N = 1) and 1–2 (N = 8).

PHRYNOSOMA CORNUTUM (Texas Horned Lizard). **REPRODUCTION**. To date, only four studies exist describing the nesting behavior of *P. cornutum* in the wild; these reports describe 1–2 nest constructions, and all are from Texas (Edwards 1896. Zool. Anz. 19:108–111; Strecker 1908. Proc. Biol. Soc. Washington 21:72, 165–170; Cahn 1926. Amer. Nat. 60:546–551; Ramsey 1956. Herpetologica 112:239–240). *Phrynosoma cornutum* is of particular conservation concern because of observed declines throughout much of its known range; the species is listed

as threatened in Oklahoma and Texas (Levell 1995. A Field Guide to Reptiles and the Law. Serpent's Tale, Lanesboro, Minnesota. 240 pp.). We augment the few behavioral data on *P. cornutum* reproduction with our observation of nesting from a native tallgrass (*Andropogon* sp.) prairie in northeastern Kansas (USA), near the northeastern limit of its range (Collins 1993. Amphibians and Reptiles in Kansas, 3rd edition. University of Kansas Press, Lawrence. 397 pp.).

We encountered an adult female *Phrynosoma cornutum* at 1530 h on 12 June 2001 along the public trail at Konza Prairie Biological Station (39°06'22.7N, 96°36'32.0W), which includes ca. 3500 ha of native Flint Hills tallgrass prairie (Reichman 1987. Konza Praire. A Tallgrass Natural History. University of Kansas Press, Lawrence. 226 pp.). Heinrich and Kaufman (1985. Prairie Naturalist 17:101–112) recorded Texas horned lizards at Konza, but did not describe reproductive behavior. We initially observed this individual for ca. 20 min directly outside a burrow located in bare soil between the prairie vegetation and the trail. The burrow appeared newly formed, with excavated soil still piled loosely around it. The burrow entrance was ca. 4 cm x 6 cm, but the interior chamber was noticeably larger, extending ca. 10–12 cm below the surface.

Upon returning at 1830 h to renew observations for another ca. 15 min, we found the female depositing eggs with only her head and front legs protruding from the burrow (Fig. 1). One strong lateral abdominal contraction preceded the laying of each egg. Throughout oviposition, the lizard often closed its eyes and our presence did not appear to disturb her. Eggs could be seen behind the lizard, but we could not estimate their number. The female finished laying after ca. 10 min and then began to scrape the excavated soil over the eggs with her hind legs, using one leg at a time. We discontinued observations when the lizard appeared to become more aware of our presence. At 2030 h, we returned to the site a final time; the lizard was gone and the burrow was completely covered. We observed no mound of soil where the entrance had been, which differs from observations of Ramsey (*op. cit.*).

Impending trail maintenance (due to heavy rains in June), led us to remove the eggs from the nest on 1 July to prevent their destruction. We removed 23 eggs that varied slightly in size and color, but were generally ca. 1 cm along the long axis and pink or off-white in color. This clutch size is at the low end of the previously reported means (mean = 23–30: range 7–30+; Burt and Hoyle 1934. Trans. Kansas Acad. Sci. 37:193–216; Howard 1974. J. Arizona Acad. Sci. 9:108–116; Fitch 1985. Univ. of Kansas Mus. Nat. His. Publ. 76:1–76), which may reflect the northern locale of our observation. The eggs were deposited in three distinct layers, each separated by one layer of soil. Strecker (*op. cit.*) and Cahn (*op. cit.*) also reported layering with soil. We also found that many eggs in the clutch were touching and somewhat adherent to one another, which generally differs from the observations of Cahn (*op. cit.*) and Strecker (*op. cit.*), who found sand between all eggs, (not just between layers). However, Strecker (*op. cit.*) did describe a *P. cornutum* nest in a hollow covered by a railroad tie that had little or no soil separating the eggs.

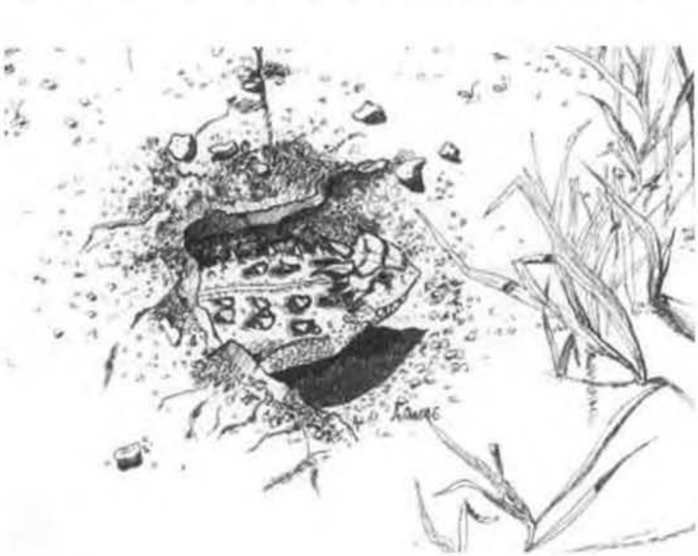

FIG. 1. Female *Phrynosoma cornutum* nesting, Konza Prairie, Kansas.

We incubated the eggs in moist vermiculite at a constant 23°C ± 1°C. On 1 August the eggs averaged 17.4 mm in length (range 13.3–18.5 mm) and 14.3 mm in width (range 13.3–15.5 mm). A dead embryo from a damaged egg found on 1 August measured 17.0 mm SVL and 25.8 mm total length. Of the 23 eggs, 10 hatched between 27 and 31 August, 77–80 days after they had been laid. Three of the eggs were desiccated when we removed them from the nest, four spoiled during incubation, and the others were accidentally punctured during incubation. Hatchlings averaged 22.4 mm SVL (range 20.8–23.8 mm) and 29.7 mm total length (range 28.2–32.7 mm). Hatchling mass was 0.8–0.9 g. The dead embryo measured 31 days earlier on 1 August was 5.4 mm shorter in SVL and 3.9 mm shorter in total length than mean SVL of these hatchlings. The SVL of the dead embryo measured 1 August was 66% of its total length, whereas average SVL of the hatchlings was 75% of their total length. The dead embryo and hatchlings had complete tails, thus, variation in percentage of total length suggests disproportionate growth between the trunk and tail. The hatchlings were kept in an open-topped plastic container with a 40-watt sun lamp (12L/12D cycle) available for basking until ambient temperatures were suitable for release. During this time, hatchlings were fed small ants and were given water ad libitum. We observed them eating and they appeared alert and healthy, despite this, all died within two days of each other at about two weeks of age.

We thank the Nature Conservancy and Kansas State University (KSU) Division of Biology, which owns and manages the Konza Prairie Biological Station, respectively. Collection of animals occurred under permit SC-066-2001 from the Kansas Department of Wildlife and Parks. Collection, care, and handling of animals in captivity followed SSAR guidelines under KSU IACUC approval. A Research Experience for Undergraduates Program-administered NSF grant in grassland ecology supported this project.

PHRYNOSOMA CORNUTUM (Texas Horned Lizard). **BEHAVIOR**. Studying diurnal activity of *P. cornutum* associated with temperature regulation, Heath (1965. Univ. California Publ. Zool. 64:97–136) found that lizards sought shade at body temperatures of 34–41°C. Shade-seeking behavior was documented as unrelated to ambient air temperature, rather reflecting substrate temperature and radiant heat from the sun. Whitford and Bryant (1979. Ecology 60:686–694) also observed shade-seeking in *P. cornutum,* recording climbing onto low shrubs for shade during "hot" conditions. This note photodocuments *P. cornutum* sitting in the shade of a human-made object, which may reflect a thermoregulatory option in an agriculturally disturbed habitat.

On 15 June 2000 at 1635 h, we observed a *P. cornutum* positioned on the shaded side of a wooden fence-post ca. 20 cm above the ground (Fig. 1). The fence separated a cattle pasture from the surrounding cotton field next to County Road 223 (Wilbarger County, Texas, USA). The pasture had moderate densities (10–15/m^2) of mostly short grasses and soil in the vicinity was loosely packed sand. Air temperature was 36.8°C, the substrate temperature (measured at several points between the surface and 7 cm of depth) in sunlight was 38.9°C and 38.3°C in the area shaded by the fence-post, and relative humidity was low (20.3%). The horned lizard, which we observed on the shaded side of the fence-post for 30 min, made no movement during the observation interval and had its eyelids partly closed. Subsequent capture revealed it to be an adult male 9.4 cm SVL and weighing 41.3 g. We noted several harvester ant (*Pogonomyrmex* sp.) mounds in the turn-row of the cotton field and pasture opposite the fence. No ant mounds were observed in the planted area of the cotton field

Climbing the shaded side of the fence-post is novel because it was a fairly smooth human-made object. Only low-growing plants have been documented as perch sites for *P. cornutum* (Whitford and Bryant, *op. cit.*). The lizard might have also been using the perch as an escape from predators; however, because substrate temperatures were within the range of body temperatures over which shade-seeking has been documented (Heath, *op. cit.*), we suggest the non-mutually exclusive thermoregulatory hypothesis for the observed behavior. Lastly, this observation illustrates one way in which the Texas horned lizard can utilize agriculturally impacted areas.

PHRYNOSOMA MODESTUM (Round-tailed Horned Lizard). **RAIN-HARVEST DRINKING BEHAVIOR**. Rain harvesting is a behavior that lizards use to move rainwater collected on the skin to the mouth for ingestion using (1): inter-scalar capillary forces associated with the integument and/or (2) postural behaviors. It has been reported in two species of horned lizards (Sherbrooke 1990. J. Herpetol. 24:302–308; Peterson 1998. Southwest. Nat. 43:391–394) and five agamids (Gans et al. 1982. Amphibia-Reptilia 3:57–64; Schwenk and Greene 1987. J. Herpetol. 21:134–139; Sherbrooke 1993. J. Herpetol. 27:270–275; Vesely and Modry 2002. J. Herpetol. 36:311–314). Here, I report evidence suggesting that *Phrynosoma modestum*, a small species (43–66 mm adult SVL) in the genus (Sherbrooke and Middendorf 2001. Copeia 2001:1114–1122) with particularly smooth dorsal skin (lacking elongated spines), also utilizes a form of rain-harvesting to collect water on its integumental surfaces for transport to the mouth for drinking. I have assembled observations collected over more than two decades to clarify the occurrence of this phenomenon in *P. modestum*. Unless otherwise noted, observations were made on lizards from eastern Cochise Co., Arizona, and Hidalgo Co., New Mexico (all USA).

At ca. 1700 h on 15 July 1977 while a thunderstorm threatened, 12 adult *P. modestum* (44–65 mm SVL) collected 6 km NE Portal, San Simon Valley, Arizona, were individually tested on a rock in the field as a series of water droplets (ca. 20–40) was released onto their heads from an eye dropper over 3-min periods. When presented with water in this manner, four of these lizards exhibited slow opening and closing jaw motions (upper and lower labial scales barely parted from one another back to the angle of the jaw) suggesting that ingestion of water was occurring; all but one showed movements of the nictitating membrane, suggesting that lizards were wiping water off their eyes. In contrast to experiments with *P. cornutum* (Sherbrooke 1990, *op. cit.*), water droplets beaded on the backs of the *P. modestum* and no evidence of capillary flow was seen.

On 13 June 1984, 10 adult *P. modestum* (50–64 mm SVL; 4 females, 6 males) were individually placed into 250 ml glass beakers surrounded by opaque white paper. Five ml of water was pipetted into each beaker, which covered the bottom of each beaker to a depth of 1 mm except at the sides, where an adhesion meniscus caused water to rise an additional 2 mm. Lizards were observed to ensure that they did not move in a manner that would augment

wetting of skin surfaces. Final examination after 30 min showed that all lizards had dry heads, and the back was dry in all but one animal (this was the largest individual, which could only fit into the beaker with its limbs appressed against the container walls); all lizards had the legs and ventral surfaces wetted. These results contrast with a similar experiment with 10 adult *P. cornutum*, which was conducted using 3.8-liter metal cans in which a 5-mm depth of water was placed (Sherbrooke 1988. Ph.D. dissertation, Univ. Arizona, Tucson). All but the back of one was wet after 30 min, and after 60 min, heads of all 10 were wet.

On 29 August 1984, I further tested the notion of capillary flow by examining 3 adult female *P. modestum* (56–64 mm SVL; including one from Graham Co., Arizona) under a dissecting scope to which droplets of methylene blue-dyed water had been applied to their backs. Two exhibited capillary flow of water and one did not. On 13 and 15 October 1984, four additional, similar tests were conducted on the same two lizards that exhibited capillary flow on 29 August. In one test, one lizard showed rapid inter-scalar flow of water across the skin surfaces, but in the remaining three tests, no capillary flow was observed. On 26 July 1999, I tested 4 additional adult *P. modestum* (46–58 mm SVL; 1 female, 3 males), this time applying drops of methylene blue-dyed water with a syringe onto the lizards' backs. In two cases, the water moved rapidly across the integumental surface, whereas in the other two cases it only did so slowly.

On 9 July 2001, 23 adult *P. modestum* (43–65 mm SVL; 6 females, 17 males) were used to further test inter-scalar flow of water. Methylene blue-dyed drops (0.05 ml each) were applied to the midback using a full 1 cc syringe and the spread of the water was observed for 1 min. Rate of water spread over the back varied considerably, being slow or fast, and may have been influenced by the mass of the "pool" of standing water on the back. Water appeared to move through inter-scalar channels, with a clear and narrow front a few scales wide preceding the dyed water.

On 18 June 2001, to examine ingestion of water collected on skin surfaces from simulated rainfall, I weighed 25 adult *P. modestum* not fed for the previous two days at 1500 h to the nearest 0.01 g (mean = 8.87 g, s = 2.29 g, SE = 0.46 g, range: 4.16–13.15 g) and placed them in an outdoor wire-meshed enclosure (7.0 x 3.8 x 2.4 m high) with sheet metal walls on the lower 60 cm. The substrate was sand and gravel, raked free of leaves, and the enclosure was free of food items. A sprinkler started at 1545 h simulated a heavy shower for 1 h, during which time the sun remained shining. Lizards exhibited jaw motions (duration of six continuous-jaw-motion events determined from video record was 9–20 sec with a mean rate of 1.45 jaw motions/sec) and body postures typical of rain harvesting, suggesting drinking. Postures involved extension of four limbs to raise the abdomen above the substratum, but still horizontal to it, and lowering of the head similar to *P. cornutum* (Fig. 1.; Sherbrooke 1990, *op. cit.*). Behaviors suggesting drinking were not noted after the first 20 min. Posture and water flow patterns, inter-scalar (capillary) or sheet-flow over scale surfaces, may vary with intensity of rainfall and rain droplet size (see raised hindquarters when misted, Fig. 1). Immediately after the "rain" treatment, most (N = 23) of the lizards were puffed up, suggesting inhalation and pulmonary retention of air. This may represent a defensive response (allowing flotation) to potential flooding conditions. Lizards were allowed to dry for 24 h before weighing so that water held in integumental surface channels could evaporate and its mass would not be included in the mass changes affected by water ingestion. Twenty-four animals showed weight gain (mean = 0.32 g, s = 0.22 g, SE = 0.04, range: 0.01–0.87 g; mean % body weight = 3.84%, range: 0.17–8.43%); one lizard lost 0.35 g (or 2.66% of its body weight; it may have defecated).

My data illustrate that when wetted in various ways, some of which simulate different precipitation types, *P. modestum* does not consistently exhibit rapid inter-scalar water flow that can carry water to the mouth. Although capillary flow occurs, it appears less efficient than that described for *P. cornutum* and *Moloch horridus*; interspecific differences in integumentary micro-ornamentation may play a role. Further, physical or chemical factors associated with the skin-shed cycle may influence observed differences in flow rates (Sherbrooke 1990, *op. cit.*). Nevertheless, this lizard is able to make postural adjustments to falling water droplets that result in ingestion of water through the jaws and weight gains. The lizard's stance during rain harvesting is variable, from nearly horizontal to steeply slanted, in that the head is low and the posterior abdomen is held much higher. As with *P. cornutum* under heavy rainfall conditions (Sherbrooke 1990, *op. cit.*), the slanted stance probably allows gravity to assist the flow of water draining from the entire dorsal integumental surface, not just that in capillary channels. Misting of lizards with fine droplets of water also elicits a rain-harvesting stance (Fig. 1), but makes tracing integumental water flow difficult. Nevertheless, it may be during such light rainfall events, which occur during dry seasons when animals may be water stressed, that rain harvesting plays its most vital role in water balance for these lizards (Sherbrooke 1990, *op. cit.*).

A third species of *Phrynosoma* exhibiting rain-harvesting behavior suggests that this postural behavior may be widespread in the genus. These data further indicate that the interscalar-capillary water-flow system may have a variable role among species showing postural adjustments for integumental capture of rainfall or drinking, a role which may vary with rainfall intensity. If true, such variation has the potential to contribute not only to more sophisticated phylogenetic resolution within the genus *Phrynosoma*, but to interesting comparisons that address differences and convergent similarities (in posturing and integumental components), among species of this genus and the Australian agamid genus *Moloch*, for which no postural adjustments are reported (Sherbrooke 1993, *op. cit.*; Sherbrooke 1999. Nature Australia 26:54–63), and other agamids.

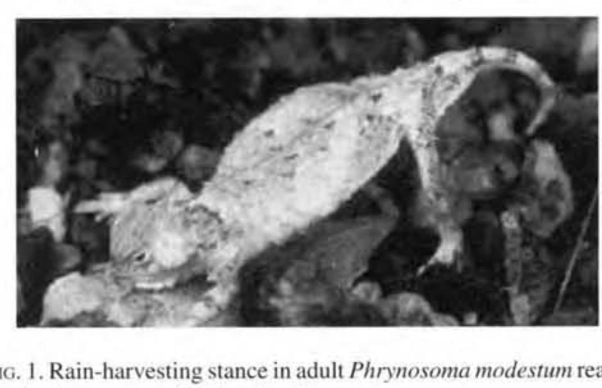

FIG. 1. Rain-harvesting stance in adult *Phrynosoma modestum* reacting to having been sprayed with misted water.

Historical Note: In June 1989, Gordon C. Creel visited me at the Southwestern Research Station and illustrated to me the behavioral response of *P. modestum* to misted water that he had recorded earlier. In June 1968, Creel found a *P. modestum* engaged in an unusual behavior in Tom Green Co. (Texas, USA) during a rain storm. He noted that the lizard's body was elevated off the ground by the hind legs resulting in a 30° forward inclination of the body and the ribs were spread laterally. Interpreting the directing of flow of water down the body to the jaw as drinking behavior, he was later able to obtain other round-tailed horned lizards to repeat the behavior and film it when artificial "rain" was applied. Portions of his filming (which I have viewed) were presented in 1968 at the Texas Academy of Science meeting in Nacogdoches, Texas, but no abstract was published (G. C. Creel, pers. comm.).

PHRYNOSOMA MODESTUM (Round-tailed Horned Lizard). **DEATH DUE TO PREY (BEETLE) INGESTION**. Prey selection involves decisions during the pursuit and capture of prey that potentially have both positive or negative consequences to predator survival, nutritional requirements and dangers posed by lethal prey defenses. Between 28 April and 12 July 2001, 29 round-tailed horned lizards (43–66 mm SVL) collected in Cochise (Arizona) and Hidalgo (New Mexico) Cos. were maintained in an outdoor wire-mesh enclosure (7.0 x 3.8 x 2.4 m high with sheet-metal walls on the lower 60 cm) at the Southwestern Research Station (1645 m elev.), in Cave Creek Canyon, Chiricahua Mountains, Arizona, USA. A pile of constantly replenished, rotting grocery-store fruit was maintained in the enclosure to serve as a breeding site for fruit flies, tiny beetles, and other attracted insects that served as a food source for the lizards. In addition, an UV light (40 cm fluorescent tube) was run in the enclosure each night to attract nocturnal insects that lizards could feed on. Four juvenile *Phrynosoma cornutum* (40–51 mm SVL) were also maintained in the enclosure. All lizards were used intermittently for behavioral studies that did not involve feeding nor absence from the enclosure for more than 48 h, but did involve drinking sprayed water. In previous seasons, individual round-tailed horned lizards thus maintained had occasionally died unexpectedly of unknown causes. Here, I report several instances of unexpected deaths attributable to ingestion of beetle taxa. These instances may provide one potential explanation for the earlier deaths.

On 30 May, an adult male *P. modestum* (62 mm SVL) was found dead in the enclosure. When dissected on 21 June, a dark bombardier beetle (*Brachinus mexicanus* Dejean, Carabidae; total length 12.9 mm) was found in the lizard's coelomic cavity, and the fore-stomach wall had a 7-mm long ragged lesion. On 20 June, a female *P. modestum* (66 mm SVL) that had laid eggs in the cage on 18 May was found dead. A black scarab beetle (*Diplotaxus* sp., Scarabaeidae; total length 11.9 mm) was discovered in the coelomic cavity and an 11-mm lesion existed in the middle portion of the stomach wall. As all of the fragile tarsi on the beetle were missing, the beetle may have burrowed out using the apices of the tibiae and small teeth on the outside of the foretibia. On 5 July, I found a dead male *P. modestum* (58 mm SVL) in the cage. It had two lesions, 8 mm and 5 mm, in its stomach wall. Several tiny unidentified black beetles were still in its stomach and a large carabid (*Helluomorphoides ferrugineus* [LeConte], Carabidae; total length 14.6 mm) was protruding from the stomach wall into the coelomic cavity. The external body walls of all three lizards were intact.

These observations support the hypothesis that these lizards died from physical injuries inflicted by ingested prey (including the chemically noxious bombardier beetle). Beetles may have been eaten in typical horned lizard tongue-flicking fashion, without being bitten or killed (Sherbrooke 1987. Herpetol. Rev. 18:11–13). Although the dietary mainstay of lizards in the genus *Phrynosoma* is ants, beetles are significant in the diet of some species (Pianka and Parker 1975. Copeia 1975:141–162). Some noxious insects, such as blister beetles (Cohen and Cohen 1990. Southwest. Nat. 35:369) and velvet ants (Manley and Sherbrooke 2001. Southwest. Nat. 46:221–222) may be successfully eaten. Under natural conditions, prey-item selection by horned lizards may be influenced by the potential some insects have to inflict internal post-ingestion injuries that can be fatal.

I thank Brett Ratcliffe for identification of *Diplotaxis* and noting the condition of the tarsi, and Terry Erwin for identification of the two carabids.

SERPENTES

COLUBER CONSTRICTOR (Racer). **REPRODUCTION.** Data on reproduction and nest sites of *C. constrictor* in agricultural regions of the midwestern U.S. are few. On 23 April 1998, we collected a 91.4 cm SVL female *C. constrictor* at the Middle Fork Fish and Wildlife Area (MFFWA), Vermilion County, Illinois, USA. The snake was taken to the laboratory, implanted with a radio transmitter for a study of habitat use (Keller and Heske 2000. J. Herpetol. 34:558–564), then released one day after surgery (26 April) near the site of capture. On 5 May, this female was observed copulating with a male.

On 30 June, the radio signal from this female originated underground in an old field at MFFWA, ca. 4 m W of the forest-field edge. The signal location did not change for the next month. Believing that the snake had died, we proceeded to dig it up on 27 July. Instead of the snake, a clutch of eggs, damaged in the process, was discovered. In all likelihood, the transmitter had accidentally been placed in the oviduct and was passed during oviposition. Several live embryos, without pigment and ca. 50 mm in length, were observed. We could not determine exactly how many eggs were in the clutch because of the damage, but 5 eggs were intact and at least 2 were broken. The temperature at the eggs was 24.4°C, and the surface soil temp was 30.8°C. The intact eggs were taken to the laboratory and incubated on vermiculite in a ventilated container sitting in a water bath of 28.1°C. All 5 eggs hatched on 16 August. Maximum length of incubation would have been 47 days.

The oviposition site appeared to be in an abandoned rodent tunnel ca. 2 cm below the surface. Details of soil characteristics and nearby plants can be found in Keller (2000. Habitat Use by Three

Species of Snakes at the Middlefork Fish and Wildlife Area, Vermilion County, Illinois, with Notes on their Natural History. MS thesis, Univ. Illinois Urbana-Champaign. 40 pp.). Ernst and Barbour (1989. Snakes of Eastern North America. George Mason University Press, Fairfax, Virginia. 282 pp.) note mammal burrows, rotting logs and stumps, and old sawdust piles as oviposition sites for *Coluber constrictor*, with 9–12 eggs per clutch (up to 31 reported) being most common. Adequate nest sites are crucial to the persistence of snake populations in areas of decreasing habitat and declining snake populations such as regions dominated by row-crop agriculture. If shallow burrows are common oviposition sites for *C. constrictor*, cultivation during early summer could reduce the availability of nest sites and destroy clutches of incubating eggs.

Submitted by **W. LAWRENCE KELLER**, Department of Natural Resources and Environmental Sciences, University of Illinois Urbana-Champaign, Urbana, Illinois 61801, USA (e-mail: w-keller@uiuc.edu), and **EDWARD J. HESKE**, Illinois Natural History Survey, 607 East Peabody Drive, Champaign, Illinois 61820, USA.

CROTALUS VIRIDIS OREGANUS (Northern Pacific Rattlesnake). **DIET.** The diet of *Crotalus viridis* includes rodents, birds, lizards (Macartney 1989. Herpetologica 45:299–304), and conspecifics (Gloyd 1933. Copeia 1933:98; Klauber 1956. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Univ. California Press, Berkeley. 1476 pp.; Lillywhite 1982. J. Herpetol. 16:95). We report the first incidence of non-cannibalistic ophiophagy by *C. viridis*. An adult male *C. v. oreganus* (716 mm SVL) had partially digested an adult male rubber boa (*Charina bottae*), 220 mm neck–vent, in its stomach. The *C. v. oreganus* was collected by Aaron Feiner on 21 July 2000 in Stanislaus National Forest, California, USA. Both snakes are part of the herpetological collections of the University of Michigan Museum of Zoology (UMMZ 227199).

ELAPHE OBSOLETA (Black Rat Snake). **BEHAVIOR.** Behavior is known to influence thermoregulation in lizards and snakes. For example, snakes can limit their heat loss by coiling themselves, and lizards can increase their heating rate by positioning their back at a right angle to the sun's rays, or minimize their heat absorption by facing the sun (Heatwole and Taylor 1987. Ecology of Reptiles. Surrey Beatty & Sons Pty Limited, Chipping Norton, NSW, Australia. 325 pp.; Lillywhite 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp.422–477. Macmillan Publishing Co., New York; Tracy 1982. *In* Gans and Pough [eds.], Biology of the Reptiles, pp. 275–321. Academic Press, New York; Stevenson 1985. Am. Nat.126:362–386). Dorsoventral flattening of the body is another behavioral mechanism for increasing the rate of heating as this allows a greater area to be exposed to the sunlight than might be in a normal posture. This flattening of the body has been observed in lizards when ambient temperatures are cool, but the behavior is little known in snakes (Cogger 1974. Australian J. Zool. 26:653-672; Heatwole and Johnson 1979. Zool. J. Linn. Soc. 65:83-101; Heatwole and Taylor, *op. cit.*).

Dorsoventral flattening was observed in a snake on 15 April 2000, when the herpetology class at Yale University sponsored a field trip to Hurd State Park in East Haddem, Connecticut, USA. Despite several warm and sunny spring days from the end of March into the beginning of April (i.e., afternoons reaching an average of 22°C), the entire week prior to this trip was characterized by cold cloudy days with temperatures ranging from 0°C to 4°C. The morning of the trip was overcast with a temperature of 10°C at 0930 h. Thus, the cold and cloudy conditions reduced the expectation that snakes would be visible on such a day.

At 1330 h on 15 April the temperature at Hurd State Park reached its maximum of 15°C, and the conditions were still overcast with a slight drizzle. Unexpectedly, the class discovered a large *Elaphe obsoleta* in a grassy meadow bordered by higher elevation forest and rock ledges. The activity period for *E. obsoleta* is reported to begin around 20–27 April in southern New England and New York (Klemens 1993. Bulletin 112: State Geol. Nat. Hist. Surv. Connecticut. Hartford, Connecticut. 228 pp.), but Ernst and Barbour (1989. Snakes of Eastern North America. George Mason University Press, Fairfax, Virginia. 282 pp.) report activity as early as late March. Thus, our sighting (15 April) of *E. obsoleta* was in accordance with the start of the snake's activity period in this region.

Upon discovery, the snake remained stiff and motionless in the wet grass as we approached it to within 1 m. Initially it appeared to be a gravid female with lumps of eggs alternating along the length of the body. Closer inspection revealed that the body was flattened and contraction of body muscles caused a zigzag pattern along the entire body. Within a minute of being observed, the lumps disappeared, and the motionless snake began to move. It first started flicking its tongue, and rattling its tail defensively (Schulz 1996. A Monograph of the Colubrid Snakes of the Genus *Elaphe* Fitzinger. Koeltz Scientific Books, Havlickuv Brod, Czech Republic. 439 pp.). The snake was identified as an adult male with a total length of 98 cm. Based on natural history information for lizards we believe that this snake may have used this flattened posture to improve its ability to gain heat.

Laboratory studies of snakes have shown similar flattening behavior. Heatwole and Johnson (*op. cit.*) examined temperature changes along the body of the Australian Red-bellied Blacksnake (*Pseudechis porphyriacus*) in the laboratory with subcutaneous thermocouples. They subjected the snake to various degrees of sunlight during the winter months and reported that as the area of sunlight exposed to the surface of the snake increased from the anterior end to the posterior end, the snake progressively flattened its body. This behavioral change in body shape corresponded to sharp rises in subcutaneous temperature. In addition to the increased heat captured from an increased surface area, heating rates when the body is flattened may also be higher because the complex system of integumentary blood vessels known to exist in snakes come into closer contact with the main arterial system (Bartholomew 1982. *In* Gans and Pough [eds.], Volume 12 [Physiology C], pp. 167–211. Academic Press, New York). This

permits more efficient heat exchange between the body core and dorsal surface. Thus, the laboratory experiments of Heatwole and Johnson (*op. cit.*) appear to support our proposition regarding the utility of flattening behavior in increasing heat gain, and helps to explain our field observation of *Elaphe obsoleta*.

Laboratory studies that lack sunlight, however, have not detected behavioral changes in the dorsal surface area of snakes. A study by Lillywhite (1980. Copeia 1980:452–458) which examined behavioral thermoregulation among five species of Australian elapids (one of these species was *P. porphyriacus*, the same species studied by Heatwole and Johnson [*op. cit.*]) reported no dorsoventral change in body shape as the temperature varied between 18°C and 40°C. However, Lillywhite never exposed his snakes to conditions as cold as those in the study by Heatwole and Johnson (*op. cit.*) (e.g., the lowest temperatures reported are 18°C in Lillywhite [*op. cit.*] versus 5°C in Heatwole and Johnson [*op. cit.*]). Another study which examined the physiological responses of *E. obsoleta* and *Pituophis melanoleucus* to low ambient temperatures (ranging from 0–20°C) also fails to mention behavioral body shape changes corresponding to thermoregulation (Landreth 1972. Herpetologica 28:376–380).

These limited data suggest that sunlight may be the critical factor stimulating behavioral changes in body shape, rather than ambient temperature alone. It also helps to explain why we observed this flattening behavior in the field, despite the cool Spring temperature. Solar rays can reach the surface of the earth despite cloud cover, and it is likely that these rays, rather than ambient heat, were primarily being absorbed by the snake's dorsal surface when we encountered *E. obsoleta* on the wet field.

Other herpetologists have also observed this dorsoventral flattening behavior in nature. Herndon G. Dowling (pers. comm.) has observed this behavior in *E. obsoleta* while driving down a road in western Alachua County on a sunny day, ca. 15 March 1957. He stated that the contracted muscles made the snake "as stiff as a stick and he thought when he first picked it up that it was dead and dried out."

Jan Jenner (pers. comm.) has observed adult *Elaphe obsoleta*, *E. guttata*, and *Lampropeltis getula* lying in the contorted, zigzag posture in north-central Alabama (Talladega County). She notes that they are especially easy to spot because they seem to prefer to lie in the middle of a sunny road in early spring. When picked off the road she found that the snakes usually stay stiffly "kinked" for several seconds before reacting to being handled.

Dorsoventral flattening is not typically reported in the literature for snakes. This omission could be due to three reasons. First, most field-based thermoregulation studies on snakes have taken place when the snakes are at their peak activity period and can easily be encountered by the investigator in the field. Second, this behavior is unfavorable because it restricts the snake's ability to move, rendering it more subject to predation. Thus, snakes may restrict this behavior to activity times during cooler temperatures when their choices for thermoregulation are limited. The inability of the snake to move while flattened can be explained by the anatomical and mechanical relationship that the vertebrae and ribs have to the subcutaneous muscles (Gasc 1981. *In* Gans and Parsons [eds.], Biology of the Reptilia: Volume 11 [Morphology F], pp. 355–435. Academic Press, New York). Thus, if the muscles and bones are participating in the flattening of the body, they cannot be used simultaneously for sinusoid mobility. A third reason that explains why this behavior is not typically observed in the field is because this behavior may be limited to a small number of snake species, particularly those in temperate climates that require a thermoregulatory mechanism to protect them during drops in temperature typically experienced during the spring season.

Without field data it is difficult to say whether the *E. obsoleta* we observed on the field was heating or cooling its body. The cool ambient temperature makes it unlikely that this snake would choose to use a mechanism of body cooling that rendered it inactive and more susceptible to predation. Therefore, although heat gained by absorbing solar radiation likely outweighs heat lost by conduction to the substrate on this cold morning, we cannot dismiss the possibility that the body heat that is lost by conduction may decrease the overall benefit (in terms of an increased overall rate of heat gain) of dorsoventral flattening. Quantitative data that can explain the biological relevance of this behavior must be collected for snakes before we can be sure of the explanation for the snake behavior we observed. For this reason, we encourage scientists interested in thermoregulatory studies and dorsoventral flattening to consider studying snakes and comparing their behavioral thermoregulatory mechanisms to those known for lizards.

We thank Peter Warny and Chuck Annicelli for guiding the class through Hurd State Park on 15 April 2000, and the Department of Ecology and Evolutionary Biology at Yale University for sponsoring this field trip. Also, thanks goes to HGD and JJ for sharing their field observations, and to Christopher T. Winne for his editorial suggestions in reviewing this report.

HETERODON PLATIRHINOS (Eastern Hognose Snake). **DIET.** *Heterodon platirhinos* is often considered a toad specialist. However, frogs (*Rana pipiens*), lizards, salamanders, arthropods, birds, and mammals have been reported as prey items (Platt 1969. Univ. Kansas Mus. Nat. Hist. Publ. 18:253–420). Bullfrogs (*Rana catesbeiana*) have been consumed by captive eastern hognose snakes (Platt 1969, *op. cit.*) and a wild-caught juvenile snake disgorged a small bullfrog (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. of North Carolina Press, Chapel Hill, North Carolina. 412 pp.). Here, we report the predation upon an adult bullfrog by an adult wild hognose snake. Two hognose snakes, a male (not measured) and a female (68.8 cm SVL; 82.4 cm TL; 220 g without prey item), were encountered together at ca. 1500 h on 27 February 2001 in Tuskegee National Forest, Macon County, Alabama, USA. Upon capture, the female initiated a defensive display and regurgitated an adult male bullfrog (10.6 cm SVL; 89.7 g; 41% of the snake's mass) that had been swallowed headfirst. The frog showed no signs of digestion but the left hind leg was broken at the knee and some skin had peeled off of that leg. Both snakes were melanistic, a common feature of most Alabama populations (Mount 1975. The Reptiles and Amphibians of Alabama. Alabama Agri. Exper. Sta. Auburn, Alabama. 347 pp.). The snakes were later released at the point of capture. We thank Robert Mount and Craig Guyer for comments.

Correction: *Tupinambis* Predation

In the last issue of *Herpetological Review*, we provided the first record of amphibian prey identified to species for *Tupinambis teguixin* (Souza et al. 2002, Herpetol. Rev. 33:209). Review of the herpetological collection in the Centro de Estudos e Pesquisas Biológicas (CEPB) together with new data provided by Ayrton K. Péres Jr. and G. R. Colli (Universidade de Brasília - UnB, Brazil), who are reviewing the systematics of *Tupinambis*, allowed us to redetermine specimen CEPB/IFS 227-01 from our report as a juvenile *T. merianae*. *Tupinambis merianae* is a terrestrial forager reported to feed primarily on fruits, invertebrates (annelids, gastropods, arachnids, and insects), and small vertebrates (toads [*Bufo* sp.], owls [probably *Otus* sp.], and rice rats [*Oryzomys* sp.]; Avila-Pires 1995. Zoologische Verhandelingen 209:1–706; Kiefer and Sazima 2002. Amphibia-Reptilia 23:105–108). Thus, our record of amphibian prey applies to *T. merianae*.

GYRINOPHILUS PALLEUCUS (Tennessee Cave Salamander). USA: TENNESSEE: Bedford Co: Privately owned cave near Normandy, Tennessee. 16 February 2002. Stephen T. Samoray, Heather Garland, Thany Mann, Brian Roebuck, Lynn Roebuck, Joseph C. Douglas, Melinda Welton, and John Noel. Austin Peay State University Museum (APSU Color Slide 3325). Photos by Lynn Roebuck. Verified by Addison Wynn. In light of this species' status as threatened in Tennessee and because of the extremely localized habitat at this site, precise locality data are being withheld, but are on file at APSU. One individual found ca. 75 m inside cave in a shallow pool to the left and below the main passage, at or slightly above stream level. The pool was 0.5–1 m deep with a silt bottom. New county record (Redmond and Scott 1996. Austin Peay State Univ. Center Field Biol. Misc. Publ. 12:1–94); fills a gap between previous sightings in the Nashville Basin and on the Western Escarpment of the Cumberland Plateau.

Submitted by **STEPHEN T. SAMORAY**, Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA and **HEATHER R. GARLAND,** Cave Program Coordinator, The Nature Conservancy of Tennessee, Nashville, Tennessee 37212, USA.

PLETHODON ANGUSTICLAVIUS (Ozark Salamander). USA: ARKANSAS: Johnson Co.: Ozone Recreation Area, Ozark National Forest NE, NE, Section 28, R23W, T12N (N35.6725° W093.4436°). 9 April 2002. K.J. Irwin. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27173). Verified by Stan Trauth. Two juveniles in leaf litter along margin of ephemeral stream in mature upland oak-hickory forest. First record for county and fills hiatus between records in Franklin and Pope counties (Trauth, Robison, and Plummer, ms. in prep.).

Submitted by **KELLY J. IRWIN**, Arkansas Game and Fish Commission, 915 East Sevier Street, Benton, Arkansas 72015, USA; e-mail: kirwin@agfc.state.ar.us.

PSEUDOBRANCHUS STRIATUS (Northern Dwarf Siren). USA: FLORIDA: Santa Rosa Co: Vicinity of Chumuckla Springs, in the mucky bed of a seepage streamlet draining the northern valley wall of McDavid Creek, 100 m upstream from its confluence with Escambia River in W 1/2 of Section 30, T4N, R30W (30°50'00"N, 87°17'30"W). 6 June 2002. D. Bruce Means and Guy H. Means. A series of six juveniles scraped from the fluid muck developed from the litter of baldcypress (*Taxodium distichus*) and black tupelo (*Nyssa sylvatica*) in the perennial seepage of the local surficial aquifer. Florida Museum of Natural History (UF 132983–87). Verified by Paul E. Moler and Kenneth L. Krysko. Santa Rosa Co. was included on the range map for this species in Ashton and Ashton (1988. Handbook of Reptiles and Amphibians of Florida, Part 3, The Amphibians, Windward Publ., Miami, Florida. 191 pp.) but voucher specimens on which this record is thought to have been based cannot be located (Ray Ashton, Kenneth L. Krysko, pers. comm.). This collection verifies the species in Santa Rosa Co. and extends the range of the genus about 115 km WNW of the previously westernmost known site (Moler and Thomas 1982. Herpetol. Rev. 13:130).

Submitted by **D. BRUCE MEANS** and **GUY H. MEANS**, Coastal Plains Institute and Land Conservancy, 1313 Milton Street, Tallahassee, Florida 32303, USA and Florida Geological Survey, 903 West Tennessee Street, Tallahassee, Florida 32314, USA.

ANURA

AGALYCHNIS SALTATOR. HONDURAS: GRACIAS A DIOS: Kaska Tingni (14°48'N, 84°46'W), 70 m elev. 27 July 2001. James R. McCranie, Josiah H. Townsend, and Larry D. Wilson. USNM 549333–43 (11 adults); SMF 81522–23 (2 adults). Verified by Steve W. Gotte (USNM specimens) and Gunther Köhler (SMF specimens). Previous Honduran records are one adult female collected ca. 90 km N of the new locality and a second adult female collected ca. 40 km NW of the new locality. (McCranie and Wilson 2002. The Amphibians of Honduras. SSAR, Contrib. Herpetol. 19:i–x, 1–625).

ELEUTHERODACTYLUS AUGUSTI CACTORUM (Western Barking Frog). USA: ARIZONA: Pima Co: Quinlan Mts. (31°58.187N, 111°36.620W). 24 July 2001. E. F. Enderson. First county record. Extends range ca. 74 km NW (Slevin 1931. Copeia 1931 [3]:140–141). Photo voucher deposited at the University of Arizona (UAZ 54046–PSV). Verified by Caren S. Goldberg.

Submitted by **ERIK F. ENDERSON**, 3234 East Patricia Street, Tucson, Arizona 85716, USA.

HYLA ELEGANS. BRAZIL: PARANÁ: Municipality of Morretes (25°23'S, 48°52'W), Porto de Cima. 03 and 05 February 2002. Rodrigo Lingnau. Museu Nacional, Rio de Janeiro (MNRJ 29756 and 29757). Verified by José P. Pombal Jr. Collected in Atlantic Forest. Previously known from the states of Bahia to São Paulo, Brazil (Frost 1985. Amphibian Species of the World. Allen Press and Association Systematics Collections, Lawrence, Kansas), in Atlantic forest, from sea level to ca. 800 m (Lutz 1973. Brazilian Species of *Hyla*. Univ. Texas Press, Austin), and from state of Minas Gerais in localities of transition Atlantic forest–Cerrado and Caatinga Domains (Nascimento and Feio 1999. Herpetol. Rev. 30:50). New record for the State of Paraná.

Submitted by **RODRIGO LINGNAU** and **ROGÉRIO P. BASTOS**, Departamento de Biologia Geral/ICB/UFG, caixa postal 131, 74001–970, Goiânia, GO, Brazil.

HYLA REGILLA (Pacific Treefrog). MÉXICO: BAJA CALIFORNIA SUR: San Juan de la Costa (24°21.4'N, 110°42.9'W), 53 m elev. 16 December 2001. Ricardo A. Escobar III, Timothy M. Youmans, and Jessie L. Grismer. La Sierra University Photographic Collection (LSUPC-F1387). Verified by L. Lee Grismer. Record fills a 145 km distributional gap between oases of the La Presa region and San Pedro (Grizmer 2002. Amphibians and Reptiles of Baja California, including its Pacific Islands and the Islands in the Sea of Cortez. Univ. California Press, Berkeley. 413 pp). Frogs were observed in high densities midday along a rocky stream that ran through the oasis.

Submitted by **RICARDO A. ESCOBAR III** (e-mail ricaesco@hotmail.com), **TIMOTHY M. YOUMANS**, and **JESSE L. GRISMER**, Department of Biology, La Sierra University, Riverside, California 92515–8247, USA.

HYLA VERSICOLOR (Gray Treefrog). CANADA: ONTARIO: Algoma District. Thessalon Twp., 0.8 km N of Hwys 129 and 17 intersection (NAD 27: UTM Zone 17: N5127200m, E304000m). 7 June 1999. Wayne F. Weller. Royal Ontario Museum (ROM 38443 [segment 23], audio cassette tape). All tape recordings and photographs verified by Ross D. MacCulloch. Intense calling from marsh behind homes in rural setting at 2425 h. This record is the westernmost location among 17 others where calls were recorded (ROM 38443 [segments 6 to 22], audio cassette tape), and 9 other locations where calling was noted within 650 km^2 of the Thessalon/Basswood Lake area. Algoma District. Tarentorus Twp., N of Kinsman Park, Sault Ste. Marie (NAD 27: UTM Zone 16: N5163800m, E708600m). 14 June 2001. Wayne F. Weller. Royal Ontario Museum (ROM 39374 [segment 19], audio cassette tape). Moderate calling from wetland behind homes in rural setting at 2210 h (air temperature 25°C) under overcast sky. This record is the westernmost location among 4 others where calls were recorded (ROM 39374 [segments 4, 5, 20, 21], audio cassette tape), and 9 other locations where calling was noted within 450 km^2 of the Sault Ste. Marie area. Algoma District. Martel Twp., 2.7 km S of Lane and Martel Twp. boundary (NAD 27: UTM Zone 17: N5211600m, E336800m). 12 June 2001. Wayne F. Weller. Royal Ontario Museum (ROM 39374 [segment 16], audio cassette tape). Intense calling from roadside wetland along Hwy 129 at 2300 h (air temperature 15°C). This record is the northernmost location among 6 others where calls were recorded (ROM 39374 [segments 1 to 3, 15, 17, 18], audio cassette tape), where 1 specimen was photographed (ROM 39373), and 11 other locations where calling was noted within 750 km^2 of the Aubrey Lake area. The documented western range limit in central Ontario is represented by specimens from the Walford/Massey area in extreme southwestern Sudbury District: Sugar Lake area (National Museum of Canada [NMC] 7456 – August 1963); Cameron Falls area (NMC 33487 – August 1990); Massey (NMC 7397, 7452, 7495 – August and September 1963). The 18 documented records from the Thessalon/Basswood Lake area extend the range 100 km W of the Walford/Massey area. The 5 documented records from the Sault Ste. Marie area extend the range 160 km to the WNW, and the 8 documented records from the Aubrey Lake area extend the range 115 km to the NW. Collectively, these 31 documented records represent the first vouchered records for Algoma District in Ontario, and substantiate observations received from several people over the period of 1974 to 1997 for Algoma District.

Submitted by **WAYNE F. WELLER**, 250 Chercover Drive, Thunder Bay, Ontario P7G 1A2, Canada.

HYLODES HEYERI (NCN). BRAZIL: SÃO PAULO: Cananéia Municipality: Ilha do Cardoso (25°06'03.6"S, 47°55'53.2"W). 25 March 2002. L. F. Toledo and R. Lingnau. Célio F. B. Haddad collection, Departamento de Zoologia, Universidade Estadual Paulista, Rio Claro, São Paulo (CFBH 4998–99). Verified by Célio F. B. Haddad. This species has a restricted distribution, known only at Municipality of Eldorado, São Paulo (type locality – Haddad et al. 1996. Copeia 1996:965–969) and Municipality of Morretes, Paraná (Lingnau 2000. Herpetol. Rev. 31:251). This is the first record of the species on this island and extends its distribution ca. 65 km SE from the type locality.

Submitted by **LUÍS FELIPE TOLEDO**, Departamento de Zoologia, Universidade Estadual Paulista, caixa postal 199, cep 13506-900, Bela Vista, Rio Claro, São Paulo, Brazil (e-mail: toledolf@hotmail.com) and **RODRIGO LINGNAU**, Departamento de Biologia Geral, Universidade Federal de Goiás, caixa postal 131, cep 74001-970, Goiânia, Goiás, Brazil (e-mail: rlingnau@lycos.com).

INSUETOPHRYNUS ACARPICUS. CHILE: IX Region (Valdivia): Rio Queule (39°38'S, 73°14'W) 124 m elev. January 2002. E. R. Soto and M. Méndez. Herpetological collection of Departamento de Biología Celular y Genética de la Universidad de Chile. Santiago (DBGUCH 3102, 3114, 3125–26, 3128, 3130). Verified by A. Veloso. Colegual Alto (39°24'S, 73°06'W), 10 km E of Queule, 500 m elev. January 2001. F. Torres-Pérez and H. Ibarra-Vidal. Zoological collection of Museo de Zoología de la Universidad de Concepción (MZUC 26930–31). Verified by J. C. Ortíz. Previously known only from type locality, Mehuín (Barrio 1970. Physis 30:331–341); new records extends known distribution 100 km N of Mehuín.

KALOPHRYNUS PLEUROSTIGMA (Black-Spotted Narrow-Mouthed Frog). WEST MALAYSIA: PAHANG: Pulau Tioman. 22 March 2002. Ricardo A. Escobar III, Jesse L. Grismer, and Timothy M. Youmans. Zoological Reference Collection at The University of Singapore, Singapore (ZRC 1.9660). Verified by L. Lee Grismer. Species previously reported from southern Thailand, southward through Singapore, and again on Sumatra, Borneo, and the southern Philippines (Matsui et al. 1996. Copeia 1996:440–445). One juvenile (14 mm SVL) was found during the day hopping

through the leaf litter along the partially decayed base of a living dipterocarp tree on Gunung Kajang (02°46'40"N, 104°10'48"E). First record for Pulau Tioman (Grismer et al. 2002. Herpetol. Rev. 33:26–29), and extends Malayan distribution eastward to the Serabuat Archipelago.

Submitted by **RICARDO A. ESCOBAR III** (e-mail ricaesco@hotmail.com), **JESSE L. GRISMER**, and **TIMOTHY M. YOUMANS**. Department of Biology, La Sierra University, Riverside, California 92515–8247, USA.

PHYLLOBATES VITTATUS (Golfodulcean Dart Frog). COSTA RICA: SAN JOSE: Tres Piedras, 15 km NW of Platanillo, 26 km SW of San Isidro de General (9°19'30"N, 83°52'00"W), Quebrada Terciopelo. 25 January 2001. Mason Ryan. Verified by Federico Bola Hos and Gerardo Chavez. Museo de Zoologia de la Universidad de Costa Rica (MZUCR). MZUCR 15981. This colorful, secretive dendrobatid is endemic to the Golfo Dulce region of southwestern Costa Rica. Herein I report a 75 km extension north of the Golfo Dulce region, and a new provincial record for San Jose. An unsubstantiated observation was made 17 km N of Dominical in Matapalo (9°19'45"N, 83°80'00"W) on 21 February 2001. A male was observed calling along a stream, but I did not have the landowner's permission to collect animals. These extensions are especially interesting because the climate changes from very humid to sub-humid from south to north (Campbell 1999. *In* W. E. Duellman [ed.], Patterns of Distribution of Amphibians: A Global Perspective, pp.111–210, Johns Hopkins Univ. Press, Baltimore, Maryland), and Tres Piedras and Matapalo are roughly in the middle of the moist southern and drier northern life zones, respectively. These new localities suggest that *P. vittatus* is able to occupy a slightly drier life zone than previously thought.

Submitted by **MASON RYAN**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA.

PHYLLODYTES KAUTSKYI (NCN). BRAZIL: BAHIA: São José do Macuco, Fazenda Unacau (15°09'S, 39°18'W), 15–22 October 1986. M. T. Rodrigues, field number 86.7227, 86.7415. Museu de Zoologia, Universidade de São Paulo, São Paulo, Brazil (MZUSP 63672–73). Verified by C. A. G. Cruz. Previously known only from the type locality in the State of Espírito Santo, southeastern Brazil (Peixoto and Cruz 1988. Rev. Brasil. Biol. 48:265–272; Frost 2002. Amphibian Species of the World: An Online Reference. V2.21 [15 July 2002] http://research.amnh.org/herpetology/amphibia/index.html. First state record; extends northern range ca. 600 km airline from the type locality.

Submitted by **OSWALDO LUIZ PEIXOTO**, Departamento de Biologia Animal, Universidade Federal Rural do Rio de Janeiro, 23851–970 Seropédica, RJ, Brazil, and **ULISSES CARAMASCHI**, Departamento de Vertebrados, Museu Nacional/UFRJ, Quinta da Boa Vista, 20940-040 Rio de Janeiro, RJ, Brazil.

RANA AURORA (Red-legged Frog). CANADA: BRITISH COLUMBIA: QUEEN CHARLOTTE ISLANDS (HAIDA GWAII): GRAHAM ISLAND: ca. 3.5 km SW of village boundary of Port Clements on the banks of Yakoun River. 53°38'20"N, 132°12'40"W. 3 July 2002 (locality 1). L. Hyatt, K. Ovaska, L. Sopuck, J. Gray. Adult, 56 mm SVL. Royal British Columbia Museum, RBCM 1945.00. Verified by Theodore M. Davis. First record of the species from the archipelago and the northernmost reported locality (ca. 400 km north from the species' known distributional limits on Vancouver Island and mainland British Columbia). The specimen was found along a grassy riverbank about 3 m from the water's edge in an old growth stand of sitka spruce (*Picea sitchensis*). We also observed the species at nine other localities. Three of these (localities 2–4) were northeast and southeast of Port Clements adjacent to Hwy 16 in roadside ditches and ponds. Locality 2: Mallard Creek. 53°42'2"N, 132°7'58"W. 3 July 2002. 2 adults and 1 juvenile. Personal photograph files of KO. Locality 3: ca. 3.5 km NE of the village boundary. 53°43'15"N, 132°7'40"W. 30 July 2002. 1 juvenile. Locality 4: Kumdis Creek by Eli Tingley Bridge, ca. 4 km SE of the village boundary. 53°39'54"N, 132°7'35"W. 30 July 2002. 1 juvenile.

The remaining six localities (5–10) were south of Port Clements in a mixed stand of old growth and second growth forest, where the species was widespread. Locality 5: 53°34'8"N, 132°6'39"W. 1 and 2 July 2002. 4 observations of juveniles and adults. Locality 6: 53°34'19"N, 132°6'57"W. 30 July 2002. 1 adult and 1 juvenile. Locality 7: 53°33'52"N, 132°5'36"W. 30 June 2002. 1 juvenile. Locality 8: 53°34'25"N, 132°6'7"W. 28 July 2002. 1 adult. Locality 9: 53°34'31"N, 132°6'14"W. 28 July 2002. 1 adult. Locality 10: 53°34'25"N, 132°6'47"W. 29 July 2002. 2 adults. Personal photograph files of KO. The frogs were found in or adjacent to a creek, bog pools, and lakeshores, and ranged in size from juveniles (SVL ca. 30 mm) to large adults (SVL up to 78 mm). The straight-line distance between the two farthest localities (3 and 7) was about 18 km.

Previously, only two species of amphibians were known from the archipelago: *Bufo boreas* (Western Toad) and *Pseudacris* (= *Hyla*) *regilla* (Pacific Treefrog). *Bufo boreas* is native to the islands (Green and Campbell 1984. Amphibians of British Columbia, British Columbia Provincial Museum Handbook 45), whereas the presence of *P. regilla* appears to be the result of a primary introduction in the early 1960s, multiple secondary introductions thereafter, and dispersal from these points of origin (Reimchen 1991. Can. Field-Nat. 105:288–290). *Rana aurora* may also have been introduced, although no record of such an event exists. Four of our records (1–4) are from areas that receive frequent human use. The remaining localities, however, are from a more remote area, accessible only through hiking from a logging road. This suggests that, if introduced, the species has dispersed throughout the forest and hence has been present in the area for many years. The possibility that the species is indigenous cannot be ruled out without further information on its distribution and genetic relationships to populations farther south.

The first observations took place while we were conducting surveys for Weyerhaeuser Canada, Nanaimo office, and we thank Glen Dunsworth for his support. Janet Gray, Kelly Sendall, Christian Engelstoft, and Brian Watson also provided assistance.

RANA CATESBEIANA (American Bullfrog). USA: COLORADO: WASHINGTON CO: pond at Messex State Wildlife

Area, County Road P, 0.6 mi. N junction County Road 59 (UTM: 0633439, 4475535). 9 July 2002. UNC-MNH 4244. Verified by David Chiszar and Hobart M. Smith. First county record (Hammerson 1999. Amphibians and Reptiles of Colorado. Second Ed. Univ. Colorado Press, Niwot. xxvii + 484 pp.). The bullfrog is an invasive species in Colorado and now appears to be established in most permanent waters of the eastern plains.

Submitted by **RON MALECKI, AMBER LAWSON, LORI CRAFT,** and **STEPHEN P. MACKESSY**, Department of Biological Sciences, University of Northern Colorado, 50 120th Street, CB 92, Greeley, Colorado 80639-0017, USA (e-mail [SPM]: spmacke@unco.edu).

RANA CATESBEIANA (American Bullfrog). BRAZIL: RIO GRANDE DO SUL: municipality of Barão (29°22'S, 51°29'W), Arroio Canoas. 20 December 1994. J. C. Gonzales. Coleção de Anfíbios, Museu de Ciências e Tecnologia da Pontifícia Universidade Católica do Rio Grande do Sul (MCP 1539, SVL 114 mm, male). Municipality of Caxias do Sul (29°10'S, 51°10'W). 3 March 1976. T. de Lema. Coleção de Anfíbios do Museu de Ciências Naturais da Fundação Zoobotânica do Rio Grande do Sul (MCN 9930–9936, juveniles). Municipality of Caxias do Sul, Vila Cristina (29°18'S, 51°10'W). 8 May 1994. M. Borges-Martins (MCP 1468, SVL 42 mm, juvenile). Municipality of Derrubadas (27°15'S, 53°51'W). 12 December 1996. A. Kwet (MCP 2557, 59 mm, juvenile). Municipality of Erechim (27°38'S, 52°16'W). 26 September 1984. P. C. Braun (MCN 2074, male). Municipality of Gravataí (29°56'S, 50°59'W). May 2000. A. Ramirez (MCP 4062, 45 mm, juvenile). Municipality of Nova Petrópolis (29°22'S, 51°06'W), locality of Treze Colônias. 13 March 2000. M. Monzel (MCP 4970–73, 45–82 mm, juveniles). Municipality of Porto Alegre (30°02'S, 51°13'W), neighborhood of Bonfim, Parque Farroupilha. December 1997. P. C. A. Garcia (MCP 3560, 145 mm). Municipality of Tenente Portela (27°22'S, 53°45'W). 27 January 2001. A. Kwet and T. Miranda (MCP 4535–38, 49–61 mm, juveniles). Municipality of Veranópolis (28°56'S, 51°32'W): Rio das Antas. 13–16 October 1998. G. Vinciprova. Coleção de Anfíbios do Departamento de Zoologia, Instituto de Biociências, Universidade Federal do Rio Grande do Sul (UFRGS 2093). Municipality of Viamão: Vila de Itapuã (30°16'S, 51°01'W), source of Arroio Amoras. 20 March 2001. F. Vilela (UFRGS 2092, two larvae). SANTA CATARINA: municipality of Jaraguá do Sul (26°29'S, 49°04'W), locality of Francisco de Paula. 15 January 1993. M. A. A. da Silva. (MCP 1256, 1260, 53 and 67 mm, juveniles). All specimens verified by A. Kwet, Staatliches Museum für Naturkunde, Stuttgart, Germany. These are the first records of invasive populations of this frog in Santa Catarina and extends considerably the known distribution in Rio Grande do Sul, currently only reported from Turvo State Park (Kwet 1999. Salamandra 35:19–36). The species is widespread in the northern and central portions of Rio Grande do Sul, and recent additional sightings (lacking voucher specimens) have been made by us. Records of invasive populations in Brazil include Paraná (Bernarde and Machado 2001. Cuad. Herpetol.14:93–104) and São Paulo (Guix 1999. Grupo Estud. Ecol. Ser. Doc. 2:32–34). The known range of this species now includes all southern Brazilian states. Introductions are believed to be associated with cultivation and meat production since the 1930's. We believe that there has been a recent increase in distribution of this species due to changes in agricultural land use.

SCAPHIOPUS HOLBROOKII (Eastern Spadefoot). USA. TENNESSEE: BLOUNT CO.: Candora Rd. 12 April 2001. LA Welch. Verified by B. T. Miller. Middle Tennessee State University (MTSU 120A). New county record, decreases suspected distribution hiatus in eastern Tennessee (Redmond and Scott 1996. Atlas of Tennessee Amphibians. Center for Field Biol. Austin Peay St. Univ. Misc. Pub. No.12. 94 pp.).The specimen was observed foraging and was photographed following an evening rain shower.

Submitted by **LINN ANN WELCH**, Radnor Lake State Natural Area, Nashville, Tennessee 37220, USA, **JUDY DULIN**, 329 Candora Road, Maryville, Tennessee 37804, USA, and **ROBIN PEELER**, Picket State Park 4605 Picket Park Hwy., Jamestown, Tennessee 38556, USA.

SPEA BOMBIFRONS (Plains Spadefoot). USA: MONTANA: TOOLE CO: Goedertz Lake on SW edge of Kevin (Sec. 34/35, T35N, R3W; UTM Zone 12: N5399810m, E428802m). 15 July 2002. Whisper Maillet. USNM 550134–5. Verified by Steve Gotte.

Extends known range in Montana ca. 64 km NW of sighting along Marias River by Mosimann and Rabb (Copeia 1952:23–27). Adults were first heard calling 25 May 2002. On 21 July, numerous metamorphs were observed moving west of Goedertz Lake. An extended drought in this area ended spring 2002.

Submitted by **WHISPER R. MAILLET, JANENE LICHTENBERG**, Confederated Salish and Kootenai Tribal Wildlife Department, P.O. Box 278, Pablo, Montana 59855, USA, and **J. KIRWIN WERNER,** Salish Kootenai College, P.O. Box 117, Pablo, Montana 59855, USA.

TESTUDINES

APALONE FEROX (Florida Softshell). USA: FLORIDA: Jefferson Co: Wacissa River, Goose Pasture, Aucilla Wildlife Management Area (30°12.186'N, 83°58.156'W). Hatchling captured in shallow water. 25 July 2002. Matthew J. Aresco. Verified by K. L. Krysko. Color Slide UF 133886. First county record (Iverson and Etchberger 1989. Florida Scientist 52:119–144; Ashton and Ashton. 1991. Handbook of Reptiles and Amphibians of Florida, Part Two: Lizards, Turtles, and Crocodilians. Windward Publ., Miami, Florida. 191 pp.). On 5 June 2002, a nesting female *A. ferox* was observed at the intersection of Sawdust Pile Rd and the unnamed north-south road that parallels the west side of the Wacissa River (A. F. Johnson, Florida Natural Areas Inventory, Tallahassee, Florida, pers. comm.).

Submitted by **MATTHEW J. ARESCO, MARGARET GUNZBURGER**, and **JOSEPH TRAVIS**, Department of Biological Science, Florida State University, Tallahassee, Florida 32306–1100, USA (e–mail [MJA]: aresco@bio.fsu.edu.)

APALONE SPINIFERA HARTWEGI (Western Spiny Softshell). USA: COLORADO: Phillips Co.: Haxtun Pond on County Road 3, 0.5 mi. S junction County Road 28. (UTM: 0699337, 4499173). 26 June 2002. UNC-MNH Photograph #30. Verified by David Chiszar and Hobart M. Smith. First county record (Hammerson 1999. Amphibians and Reptiles of Colorado. Second Ed. Univ. Colorado Press, Niwot. xxvii + 484 pp.).

Submitted by **RON MALECKI, AMBER LAWSON, LORI CRAFT,** and **STEPHEN P. MACKESSY**, Department of Biological Sciences, University of Northern Colorado, 501 20th Street, CB 92, Greeley, Colorado 80639-0017, USA (e–mail [SPM]: spmacke@unco.edu).

GOPHERUS AGASSIZII (Desert Tortoise). USA: ARIZONA: Santa Cruz Co: Atascosa Mountains, just W of Ruby Townsite; 3.5 miles S of FR 39 on FR 217 (California Gulch), ca. 1524 m elev. 13 August 2001. Tim Burkhardt and Justin Martin. Verified by David B. Wake, Museum of Vertebrate Zoology. MVZ 232831 (photo vouchers). One adult tortoise observed and photographed. The present report corroborates the unvouchered field observations by Cecil Schwalbe and Roy Averill-Murray in 1991 on the Coronado National Forest in Santa Cruz County. Their findings, summarized in Murray and Schwalbe (1993. Unpubl. report to USDA Coronado, Prescott, and Tonto National Forests, 51 pp.), included the observation of one live tortoise on Bartlett Mountain. Additonally, there is an unvouchered record included in the Nongame Data Management System (Arizona Game & Fish Department) from west of Sentinel Peak.

All of these records are from isolated pockets of Arizona Upland desert scrub (saguaro/paloverde-dominated south-facing slopes nestled among patches of grassland and lower oak woodland) within the Atascosa Mountains.

We thank Sabra Schwarz (Heritage Data Base Management System for Arizona Game and Fish Department) for providing specific locality data.

Submitted by **TIMOTHY BURKHARDT**, 49 Blossom Drive, San Rafael, California 94901, USA (e-mail: TriprionCO@aol.com), and **CECIL R. SCHWALBE**, USGS Western Ecological Research Center, Sonoran Desert Field Station, University of Arizona, Tucson, Arizona 85721, USA.

GRAPTEMYS GEOGRAPHICA (Common Map Turtle). USA: IOWA: Lafayette Co.: 1.5 mi SE of Lansing, Power Plant Road, 91°07'30"N, 43°20'30"W, R3W T98N, Sec. 2. 15 June 2002. Harlan D. Walley. Northern Illinois University HDW-NIU photograph collection 2002:1–8. Verified by Julie Ray. New county record. A nesting female having dug a nesting site 6 cm in diameter, and 127 cm in depth when observed at 1000 h, and another adjacent nest site having been exposed by predators also noted. County record; fills gap between Houston Co., Minnesota (Oldfield and Moriarty 1994. Amphibians and Reptiles Native to Minnesota, University of Minnesota Press, Minneapolis) on the north, and Crawford Co., Wisconsin (Casper 1996. Geographic Distributions of the Amphibians and Reptiles of Wisconsin, Milwaukee Publ. Museum, 87 pp.). All previous localities for Iowa are of a generalized nature, only listing the Mississippi River.

Submitted by **HARLAN D. WALLEY**, Department of Biology, Northern Illinois University, Dekalb, Illinois 60115, USA; e–mail: hdw@niu.edu.

KINOSTERNON SUBRUBRUM (Eastern Mud Turtle). USA: ARKANSAS: Perry Co.: Harris Brake Wildlife Management Area, SW, SE, Sec. 14, T4N, R17W (N34.9862° W092.7772°). 25 April 2002. K.J. Irwin. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27172). Verified by Stan Trauth. DOR adult on paved roadway, bounded by bottomland hardwood forest slough and reservoir dam planted in brome grass. First record for county and fills hiatus between records in Conway and Pulaski counties (Trauth, Robison, and Plummer, ms. in prep.).

Submitted by **KELLY J. IRWIN**, Arkansas Game and Fish Commission, 915 East Sevier Street, Benton, Arkansas 72015, USA; e–mail: kirwin@agfc.state.ar.us.

KINOSTERNON SUBRUBRUM SUBRUBRUM (Eastern Mud Turtle). USA: NORTH CAROLINA: Gates Co: 6.4 km NE of Gatesville, Merchants Mill Pond State Park (36°25'52"N, 76°41'34"W) 7 June 2002. Brian S. Gray and Mark Lethaby. Verified by Alvin Braswell. An adult female was caught, photographed, and released near the shore of family camp site #1. A photograph is deposited in the North Carolina State Museum of Natural Sciences (field no. ALB10735). New county record (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill. xiii + 412 pp.).

Submitted by **BRIAN S. GRAY**, 1217 Clifton Drive, Erie, Pennsylvania 16505, USA, and **MARK LETHABY**, 535 East 29th Street, Erie, Pennsylvania 16504, USA.

STERNOTHERUS CARINATUS (Razor-backed Musk Turtle). USA: ARKANSAS: GRANT Co.: Saline River, NW, Sec. 8, T6S, R14W (N34.2137° W092.5477°). 19 April 2002. Clifton Jackson and K. J. Irwin. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27171). Verified by Stan Trauth. Adult female drowned in commercial fishing hoop net. First record for county and fills hiatus between records in Saline and Dallas counties (Trauth, Robison, and Plummer, ms. in prep.).

Submitted by **CLIFTON JACKSON** and **KELLY J. IRWIN**, Arkansas Game and Fish Commission, 915 East Sevier Street, Benton, Arkansas 72015, USA (e-mail [KJI]: kirwin@agfc.state.ar.us).

LACERTILIA

ANOLIS CAROLINENSIS (Green Anole): BRITISH WEST INDIES: GRAND CAYMAN ISLAND: Seven-Mile Beach (grounds of Holiday Inn). 10 November 2001. Robert Powell. Bobby Witcher Memorial Collection, Avila College (BWMC 06820). First record for this species from Grand Cayman Island and only the second record for the West Indies (Eaton et al. 2001. Herpetol. Rev. 32:118). Verified by Arthur C. Echternacht. A previous report from Georgetown (F. Burton, pers. comm.), for which no specimen is available, suggests that these anoles are either established on Grand Cayman or are being imported on a regular basis. Based on pattern of dewlap color, this imported animal probably originated in an area northeast of Naples to east of Fort Myers, Florida (A. C. Echternacht, pers. comm.).

Submitted by **ROBERT POWELL**, Department of Biology, Avila University Kansas City, Missouri 64145, USA; e-mail: powellr@avila.edu.

CNEMIDOPHORUS EXSANGUIS (Chihuahuan Spotted Whiptail). USA: ARIZONA: COCHISE CO: Winchester Mountains, Davis Canyon, west-central Sec. 11, T13S R22E, Coronado National Forest, ca. 1670 m elev. UAZ 52129–30. 23 August 1999. Trevor B. Persons. Verified by John W. Wright. First record for the Winchester-Galiuro Mountains complex. Extends known range ca. 96 km WSW from the upper Gila River drainage of extreme east-central Arizona and ca. 77 km WNW from records in the northern Chiricahua Mountains of extreme southeastern Arizona (Stuart 1991. Cat. Am. Amph. Rept. 516.1–516.4).

Submitted by **TREVOR B. PERSONS**, USGS Forest and Rangeland Ecosystem Science Center, Colorado Plateau Field Station, Box 5614, Northern Arizona University, Flagstaff, Arizona 86011, USA, and **PHILIP C. ROSEN**, Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, Arizona 85721, USA.

COLEONYX VARIEGATUS (Western Banded Gecko). USA: ARIZONA: COCONINO CO: Lake Powell, Glen Canyon National Recreation Area, Antelope Point, UTM 12 461757E 4088760N (36°56'46"N, 111°25'47"W), 1152 m elev. 4 May 2001. Thomas C. Brennan, Martin J. Feldner, Hans F. Koenig, and Emily N. Taylor. University of Arizona Color Slide (54036 PSV). Verified by George Bradley. Adult female, collected at 1745 h under a flat piece of sandstone in Great Basin Desert habitat characterized by *Artemisia* and *Ephedra*, outcrops of sandstone interspersed with and areas of aeolian sand. An extensive review of museum specimens revealed one other specimen of *Coleonyx* (LACM 132434) collected at Bright Angel Creek, Grand Canyon National Park, Coconino Co., Arizona on 12 August 1929 by C. M. Bogert. The specimen collected by Bogert is from southern portion of the North Kaibab Plateau, north of the Colorado River in Arizona, where the range of *Coleonyx* was previously thought to terminate. This is the first record of *Coleonyx* from east of the North Kaibab Plateau and east of the Colorado River in northern Arizona. The nearest record of *Coleonyx* from Utah is from St. George, Washington Co., Utah (BYU 438, 523, 1450, 1544). The specimen reported herein represents a northeast range extension of ca. 100 km.

Submitted by **THOMAS C. BRENNAN**, 13201 South Wakial Loop, Apt. 3055, Phoenix, Arizona 85044, USA (e-mail: mail@brennanart.com), **MARTIN J. FELDNER** 1918 East Redfield Road, Tempe, Arizona 85283, USA (e-mail: Mjfinaz@aol.com), and **HANS F. KOENIG**, Arizona Game & Fish Department Region V, 555 North Greasewood Road, Tucson, Arizona 85745, USA.

CTENOSAURA PECTINATA (Spinytail Iguana). USA: FLORIDA: CHARLOTTE CO: 100 m W of junction State Highways 771 and 775 at the Placida public boat ramp. 29 August 2001. M. J. McCoid. Deposited at the Texas Cooperative Wildlife Collection (TCWC 84723). Verified by R. Kathryn Vaughan. Although not a new county record, this report clarifies distribution and presents an important range expansion. Bartlett and Bartlett (1999. A Field Guide to Florida Reptiles and Amphibians. Gulf Publ. Co., Houston, xiv + 280 pp.) correctly noted that *C. pectinata* are found on Gasparilla Island, Charlotte Co., Florida. They failed to note that only the northern 1/3 of Gasparilla Island is Charlotte Co. while the southern 2/3 of the island is Lee Co. Bartlett and Bartlett also incorrectly diagrammed the distribution and showed the species as occurring in Pinellas Co., Florida. For the past three to five years, there have been unsubstantiated sightings of *C. pectinata* from the Placida area (directly east of Gasparilla Island) northward several miles along the coast to the city of Englewood. Prior to this report, all documented records of *C. pectinata* on the west coast of Florida were restricted to Gasparilla Island. This specimen is not from Gasparilla Island and suggests that the species is established on west coast peninsular Florida. Two additional juvenile *C. pectinata* were also observed at the collection site.

Submitted by **MICHAEL JAMES McCOID**, Florida Fish and Wildlife Conservation Commission, 1481 Market Circle, Port Charlotte, Florida 33953, USA; e-mail: mccoid@isni.net.

EUMECES ANTHRACINUS (Coal Skink). USA: GEORGIA: PICKENS CO: Big Canoe Development, McDaniel Meadows, a conservation easement held by North American Land Trust (34.46241081N, -84.26860222W). 3 March 2002. Christopher R. Wilson. Georgia Museum of Natural History (GMNH 46877). Verified by Elizabeth McGhee. First county record (John Jensen, pers. comm.). One male individual, in breeding condition, found crawling on leaf litter in sphagnum wetland. Photographed and released. Funding for biological surveys provided by Big Canoe Company, LLC.

Submitted by **CHRISTOPHER R. WILSON**, 425 Roxanna Street, Boone, North Carolina 28607, USA; e-mail: critterfro@boone.net.

HEMIDACTYLUS BROOKII BROOKII (Brook's Gecko). THAILAND: RANONG PROVINCE: Muang District: Pak Nam Subdistrict, Ban Pak Nam; on building walls near brackish water canal (9°57'N, 98°36'E). 2000 (exact dates of collection not recorded). M. Sumontha. Institut Royal des Sciences naturelles de Belgique (IRSNB 16530–31). Verified by Ned Gilmore, Academy of Natural Sciences of Philadelphia. First verified record for Thailand. Taylor (1963. Univ. Kansas Sci. Bull. 44:687–1077) did not include this species in the Thai fauna. Chanard et al. (1999. Amphibians and Reptiles of Peninsular Malaysia and Thailand, Bushmaster Publications, Wuerselen, Germany, 240 pp.) first noted its presence in the country, but this was not based on any specific localities and those authors did not themselves confirm its occurrence (W. Grossmann, pers. comm., August 2002). This widely distributed house gecko ranges more or less continuously from Pakistan to Myanmar, with only scattered records from more eastern localities (Smith 1935. Fauna of British India Including Ceylon and Burma. Reptilia and Amphibia. Vol. II. – Sauria, Taylor & Francis, London, xiii + 440 pp., 1 map, 1 pl.). An older, doubtful record from Singapore is the only other locality from the Malay Peninsula (Denzer and Manthey 1991. Raffles Bull. Zool. 39:309–322).

Submitted by **AARON M. BAUER**, Department of Biology, Villanova University, 800 Lancaster Avenue, Villanova, Pennsylvania 19085, USA (e-mail: aaron.bauer@villanova.edu), **OLIVIER S.G. PAUWELS**, Department of Recent Vertebrates, Institut Royal des Sciences naturelles de Belgique, Rue Vautier 29, 1000 Brussels, Belgium (e-mail: osgpauwels@hotmail.com), and **MONTRI SUMONTHA**, Ranong Marine Fisheries Station, 157 M. 1 Saphan Pla Road, Pak Nam, Muang, Ranong 85000, Thailand (e-mail: knotsnake2211@yahoo.com).

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: FLORIDA: WAKULLA Co: Panacea, US 98 ca. 0.3 km N of Ochlockonee Bay, on wall of Oaks Motel, (29.979°N, 84.384°W). 24 July 2002. Steve A. Johnson, William J. Barichivich, Jennifer S. Staiger. Florida Museum of Natural History, University of Florida, Gainesville (UF 133844–133846). Verified by K. L. Krysko. We collected 3 adults with SVLs of 57, 57, and 52 mm. This apparently is the first county record for the species. *H. turcicus* individuals have been collected in Leon Co. to the north (Means 1990. Herpetol. Rev. 21:96) and in Franklin Co. to the west (Means 1996. Herpetol. Rev. 27:152). Collins and Irwin (2001. Herpetol. Rev. 32:276) overlooked the Franklin Co. record published by Means (*op. cit.*) and erroneously reported specimens collected on 4 April 2001 as a new county record.

Submitted by **STEVE A. JOHNSON**, **WILLIAM J. BARICHIVICH** and **JENNIFER S. STAIGER**, US Geological Survey, Florida Caribbean Science Center, 7920 NW 71st Street, Gainesville, Florida 32653, USA.

HEMIDACTYLUS TURCICUS (Mediterranean House Gecko). USA: FLORIDA: CHARLOTTE Co.: Port Charlotte, 2121 Ivy Street. 7 June 2002. M. J. McCoid. Texas Cooperative Wildlife Collection (TCWC 84910). Verified by R. Kathryn Vaughan. The species has a spotty distribution in Florida (Bartlett and Bartlett 1999, A Field Guide to Florida Reptiles and Amphibians. Gulf Publ. Co., Houston, Texas, xiv + 280 pp.). First record for this county.

Submitted by **MICHAEL JAMES McCOID**, Florida Fish and Wildlife Conservation Commission, 1481 Market Circle, Port Charlotte, Florida 33953, USA; e-mail: mccoid@isni.net.

LEIOCEPHALUS CARINATUS (Curlytail Lizard). USA: FLORIDA: COLLIER Co: Chokoloskee Island. North side of island at Outdoor Resorts RV Park. 7 November 2001. M. McCoid and J. DeRosa. Texas Cooperative Wildlife Collection (TCWC 84724–725). Verified by R. Kathryn Vaughan. This population represents a ca. 60 airline mile range extension from the population in the Miami area (Conant and Collins 1998. A Field Guide to Reptiles & Amphibians Eastern and Central North America. Houghton Mifflin Co., Boston, Massachusetts, xviii + 616 pp.) and is the first record for the county and west coast of Florida. Outdoor Resorts is a popular destination for vacationers from the greater Miami area and it is likely that introduction occurred through frequent travels to the area. A life-time resident of Chokoloskee Island and the manager of Outdoor Resorts (K. Brown, pers. comm.) stated that the population has been established at the resort for ca. 10 years. Although lizards are fairly common (we observed ca. 50 individuals), the population appears to be confined to the resort.

Submitted by **MICHAEL JAMES McCOID**, Florida Fish and Wildlife Conservation Commission, 1481 Market Circle, Port Charlotte, Florida 33953, USA; e-mail: mccoid@isni.net.

MESOSCINCUS MANAGUAE (Managua Skink). EL SALVADOR: SANTA ANA: N side of Lake Güija, Cantón Tecomapa, Metapán, San Diego y La Barra (14°18.5'N, 89°32'W), 425 m elev. 16 September 2000. Néstor Herrera, Ricardo Ibarra, and Roberto Rivera. YPM 12468. Found under log in tropical dry forest. SONSONATE: El Zope Mariculture Station, ca. 2 km W Playa Los Cóbanos (13°32'N, 89°49'W), 5 m elev. 10 November 1994. Oliver Komar, Ricardo Ibarra, Roberto Rivera. KU Color Transparency Collection (KU CT 11862). Both records verified by Gunther Köhler. New country record (Dueñas et al. 2001, *In* Johnson et al. [eds.], Mesoamerican Herpetology: Systematics, Zoogeography, and Conservation, pp. 93–99. Centennial Museum, Special Publ. No. 1, The University of Texas at El Paso, El Paso). Extends the western range of this species 260 airline km from the nearest locality at Punta Ratón, Choluteca, Honduras (Diaz et al. 1979. Herpetol. Rev. 10:26–27).

Submitted by **ELI GREENBAUM,** Division of Herpetology, Natural History Museum & Biodiversity Research Center, The University of Kansas, 1345 Jayhawk Boulevard, Lawrence, Kansas 66045–7561, USA (e-mail: elig@ku.edu), **NÉSTOR HERRERA,** Colonia El Roble, Av. Tecana No. 618, San Salvador, El Salvador (e-mail: ribarra@telesal.net), **OLIVER KOMAR,** Division of Ornithology, Natural History Museum & Biodiversity Research Center, The University of Kansas, 1345 Jayhawk Boulevard, Lawrence, Kansas 66045-7561, USA (e-mail: okomar@ku.edu), and **ROBERTO RIVERA,** 8° Av. Norte No. 523, San Salvador, El Salvador (e-mail: rivera@saltel.net).

SCELOPORUS JARROVII (Mountain Spiny Lizard). USA: ARIZONA: COCHISE Co.: Winchester Mountains, Davis Canyon, NW/4 of SW/4 Sec. 11, T13S R22E, Coronado National Forest,

ca. 1660 m elev. UAZ 51868. 23 August 1999. Trevor B. Persons. Verified by George Bradley. First record for the Winchester Mountains (Stebbins 1985. Peterson Field Guide to Western Reptiles and Amphibians. Second Ed. Houghton Mifflin Co., Boston, Massachusetts, 350 pp.). Together with the recent report of *S. jarrovii* from the eastern Galiuro Mountains (Enderson et al. 2001. Herpetol. Rev. 32:57–58), demonstrates broader occurrence on smaller and less elevated mountain islands near the northern end of its distribution than previously known.

Submitted by **PHILIP C. ROSEN**, Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, Arizona 85721, USA, and **TREVOR B. PERSONS**, USGS Forest and Rangeland Ecosystem Science Center, Colorado Plateau Field Station, Box 5614, Northern Arizona University, Flagstaff, Arizona 86011, USA.

SCINCELLA LATERALIS (Little Brown Skink). USA: ILLINOIS: Alexander Co: S side FR 272 and 3.2 km W Bean Ridge Road (37°15'13"N, 89°24'38"W). 12 August 2002. Kurt J. Regester and David W. Butler. Verified by Ronald A. Brandon. SIUC R-03869. Adult collected on hillside near Shawnee National Forest wildlife pond. New county record (Philips et al. 1999. Illinois Nat. Hist. Surv. Manual 8:1–282).

Submitted by **KURT J. REGESTER** and **DAVID W. BUTLER**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA

SERPENTES

BUNGARUS BUNGAROIDES. VIETNAM: YEN BAI PROVINCE: Van Yen District: Na Hau Commune: stream near 21°46'N, 104°32'E; 540 m. Collected by Nguyen Quang Truong and David Kizirian on 1 October 2001. Institute of Ecology and Biological Resources (IEBR) 1172 (= LACM FS 843). Verified by Neil Vora. First record for Vietnam (Bourret 1936. Les Serpents de L'Indochine. Imprimerie Henri Basuyau & Co, Toulouse; Welch 1988. Snakes of the Orient: A Checklist. Krieger, Malabar, Florida; Sang and Cuc 1996. Checklist of Reptiles and Amphibians of Vietnam. Sci. Tech. Publ. House, Hanoi). The species is known from a few old records in Myanmar (Burma) and India (Smith 1943. Fauna of British India, Ceylon and Burma, including the Whole of the Indo-Chinese Sub-Region. Reptilia and Amphibia. Vol. III. Taylor and Francis, London) and recent records from Nepal (e.g., Shah 1999. J. Nat. Hist. Mus. Kathmandu 18:99–111). The new specimen extends the known range nearly 1000 km SE of the closest locality (NE Putao, Myanmar; 27°22'N, 97°27'E) and is the only record from the heavily populated Red River system. No record of this species is known from vast intervening regions such as Yunnan Province, China (Zhao and Adler 1993. Herpetology of China. SSAR Contr. Herpetol., Oxford, Ohio, 522 pp.) or Lao PDR (Duckworth et al. 1999. Wildlife in Lao PDR, 1999 Status Report. IUCN, Vientiane). Meristic and other characters (1273 mm snout–vent length; 142 mm tail; hemipenis with well defined calyculate and spinose zones; 229 ventrals, [37] subcaudal pairs) are in agreement with published data (Cantor 1839. Proc. Zool. Soc. Lond. 7:33; Boulenger 1896. Catalog of Snakes in the British Museum [Natural History], Vol. 3. Taylor and Francis, London; Smith, *op. cit.*; Slowinksi 1994. J. Herpetol. 28:440–446), however, its color pattern differs from some published descriptions. For example, whereas IEBR 1172 possesses 33 rings on the trunk, the type has 48, and, in contradistinction to a specimen figured in Boulenger (1896: Plate 18: Fig. 5), the white rings in IEBR 1172 are wider, less angular, and the scale sutures in the white rings are bordered with black. This specimen seemed to be foraging around stones in the stream where it was collected and where *Bungarus candidus* and *Paa* sp. were also found.

Submitted by **DAVID KIZIRIAN** and **APRIL ERIKSSON**, Herpetology, Natural History Museum of Los Angeles County, 900 Exposition Boulevard, Los Angeles, California 90007, USA (e-mail: kizirian@nhm.org), and **NGUYEN QUANG TRUONG**, Department of Zoology, Institute of Ecology and Biological Resources, National Center for Natural Science and Technology of Vietnam, 18 Hoang Quoc Viet Str, Cau Giay, Hanoi, Vietnam (e-mail: truongqt@iebr.ncst.ac.vn).

CEMOPHORA COCCINEA (Scarletsnake). USA: ARKANSAS: Saline Co.: NE, NE, Sec. 12, T1N, R18W (N34.7537° W092.8646°). 11 April 2002. Jim Apel and K. J. Irwin. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27170). Verified by Stan Trauth. Adult found under rock in abandoned rock quarry, surrounded by pine plantation. First record for county (Trauth, Robison, and Plummer, ms. in prep.).

Submitted by **JIM APEL**, 2209 Karen Lane, Alexander, Arkansas 72002, USA and **KELLY J. IRWIN**, Arkansas Game and Fish Commission, 915 East Sevier Street, Benton, Arkansas 72015, USA (e-mail: kirwin@agfc.state.ar.us).

CZGB 3110; Municipality of Firmino Alves (14°59'S, 39°56'W). 24 November–8 December 1997. Collector unknown. CZGB 6171; Municipality of Ilhéus (14°47'S, 39°03'W). 22 September 1986. V. Nascimento. CZGB 125; Municipality of Itabela (16°35'S, 39°33'W). 25 August 1997–8 September 1997. J. Francelino. CZGB 5905; Municipality of Itacaré (14°17'S, 39°00'W). 23–29 May 1992. F. Gally. CZGB 1796; Municipality of Mascote (15°34'S, 39°18'W). 1 May–30 June 1997. Collector unknown. CZGB 5365; Municipality of Nova Ibiá (14°38'S, 39°38'W). 2 December 1997–12 March 1998. Collector unknown. CZGB 6808; Municipality of Valença (13°22'S, 39°04'W). 1 March–31 August 1993. Collector unknown. CZGB 3008. The localities listed above show that *D. i. indica* occur in wet forest and in mesophytic forest at different latitudes of southeastern Bahia. Other specimens from intervening localities are also in the CZGB collection. In some cases the dates of capture are unknown and, in these instances, dates indicate periods between visits to the farms. All specimens were verified by Ronaldo Fernandes. *Dipsas i. indica* is known from the Amazon drainage in Brazil, Colombia, Guyana, Ecuador, and Peru (Peters and Orejas-Miranda 1970. Bull. U.S. Nat. Mus. 297:87) and French Guiana (Chippaux 1986. Les Serpents de la Guyane Francaise. Orstom, Paris).

Two specimens from Bahia without locality data were previously cited as *D. bucephala* (Boulenger 1896. Catalogue of the Snakes

in the British Museum [Natural History]. London III:461) and *D. i. bucephala* (Peters 1960. Misc. Publ. Mus. Zool. Univ. Michigan 144:77). The single specimen from Bahia examined by Peters (*op. cit.*) has faded coloration. Peters considered this an intergrade between *D. i. bucephala* and *D. i. indica*, but recognized its similarity to *D. i. indica*. We suspect that the specimens examined by both authors are in fact *D. i. indica*, and we have never found *D. i. bucephala* in Bahia. Indeed, this subspecies is known in Brazil only from the central and southeastern regions (Hoge and Romano 1975. Mem. Inst. Butantan 39:51–60). The records presented here are the first for state of Bahia reliably identified as *D. i. indica*. It is likely that the specimens reported here are from a disjunct population of *D. i. indica* in the Atlantic forest not represented in other Brazilian collections.

Submitted by **ANTÔNIO JORGE SUZART ARGÔLO,** Universidade Estadual de Santa Cruz - UESC, Km 16 Rodovia Ilhéus-Itabuna, CEP 45650-000, Ilhéus, Bahia, Brazil and **FÁTIMA QUEIROZ ALVES,** Rua D, Loteamento Santa Teresa, n. 34, Banco Raso, CEP 45600-000, Itabuna, Bahia, Brazil.

DRYMOLUBER DICHROUS. BRAZIL: MINAS GERAIS: Parque Nacional do Rio Doce, near Marliéria municipality (19°43'S, 42°45'W). 27–28 April 1986. Ulisses Caramaschi. Museu Nacional, Rio de Janeiro, Brazil (MNRJ) 9297, adult male 660 mm SVL, 270 mm TL). Verified by Ronaldo Fernandes. First record from the State of Minas Gerais, and third record from the Atlantic Forest, extending the known range ca. 500 km SW of Porto Seguro, State of Bahia (Franco et al. Répteis na Estação Vera Cruz. Rio de Janeiro, Veracel Celulose, 1998).

Submitted by **PAULO PASSOS** (e–mail: ppassos@mn.ufrj.br) and **FERNANDA BRANDÃO** (e-mail: fernandabrandao@ufrj.br), Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Quinta da Boa Vista s/n, Rio de Janeiro, Rio de Janeiro, 20940-040, Brazil.

ERIDIPHAS SLEVINI SLEVINI (Slevin's Night Snake). MÉXICO: BAJA CALIFORNIA SUR: San Juan de La Costa, 80 km N of La Paz. 16 December 2001. Ricardo Escobar III, Timothy M. Youmans, and Jesse L. Grismer. La Sierra University Collection (LSUPC S3256). Verified by L. Lee Grismer. This record fills a distribution gap of ca. 100 km between Rancho La Presa and La Paz (Grismer 1996, Herpetol. Rev. 27:33–34). The specimen was found in a sandstone exfoliation on a south-facing canyon wall ca. 1 m above ground.

Submitted by **TIMOTHY M. YOUMANS, RICARDO ESCOBAR III**, and **JESSE L. GRISMER**, Department of Biology, La Sierra University, Riverside, California 92515–8247, USA (e–mail: timoyoum@lasierra.edu).

FARANCIA ABACURA REINWARDTII (Western Mud Snake). USA: TEXAS: Marion Co: 4.0 km SSW Smithland off Texas 43, vic. Kitchen's Creek watershed. 4 June 2002. C. T. McAllister. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 26994). Verified by Stanley E. Trauth. New county record partially filling six-county hiatus in NE Texas (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 421 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. of Texas Press, Austin. 437 pp.). Also reported previously from adjacent Caddo Parish, Louisiana (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. LSU Press, Baton Rouge. 300 pp.).

Submitted by **CHRIS T. McALLISTER** Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA (e–mail: chris.mcallister@tamut.edu); **JENNIFER L. HOLLIS**, Department of Biology, University of Northern Iowa, Cedar Falls, Iowa 50613, USA; and **SHELLY B. SMITH**, Department of Biology, Texas A&M University–Texarkana, Texarkana, Texas 75505, USA.

HYDROPS TRIANGULARIS NEGLECTUS. BRAZIL: PARÁ: Santarém (2°26'S; 54°42'W). Month and day of collection unknown, 1999. Linha de Pesquisa em Herpetologia da Amazônia (LPHA), Laboratório de Pesquisas Zoológicas (LPZ). Faculdades Integradas do Tapajós (FIT), Santarém, Pará State (LPHA 092). Verified by A. P. dos Santos-Jr. Species known from Trinidad and western Guiana, (Roze 1957. Acta Biologica Venezuelica 2[8]:51–95). First country record, enlarges known distribution ca. 1044 km from Mazaruny in Guiana (Roze, *op. cit.*).

Submitted by **ANDREI GUIMARÃES GUEDES, AUGUSTO RODRIGUES MAIA**, and **RUBENS NOBUO YUKI**, Linha de Pesquisa em Herpetologia da Amazônia (LPHA), Laboratório de Pesquisas Zoológicas (LPZ). Faculdades Integradas do Tapajós (FIT). Rua Rosa Vermelha, 335, Santarém, Pará, Brazil, CEP: 68.010–120 (e-mail: herpeton6@hotmail.com).

LIOPHIS MILIARIS AMAZONICUS (Common Watersnake). BRAZIL: PARÁ: Municipio Itaituba (4°17'S, 55°59'W), left bank of the Tapajós River. J. G. da Frota. 9 April 2002. Linha de Pesquisa em Herpetologia da Amazônia (LPHA), Laboratório de Pesquisas Zoológicas (LPZ), Faculdades Integradas do Tapajós, Santarém, Pará State (LPHA 2235). Verified by Rubens N. Yuki. Subspecies occurs in the Santarém municipality, Brazil, SSW to Itenez River, Beni, Bolivia, east and south into Mato Grosso, Brazil (Dixon 1983. Copeia 1983:791–802). This specimen represents the second record from the basin of Tapajós River, Pará State, and extends the range ca. 240 km S from the nearest record (Municipio Santarém), also in Pará State.

Submitted by **ALFREDO PEDROSO DOS SANTOS-JR** (e–mail: alphredojr@mailbr.com.br) and **JOSSEHAN GALÚCIO DA FROTA**, Linha de Pesquisa em Herpetologia da Amazônia, Faculdades Integradas do Tapajós, Rua Rosa Vermelha, 335, Santarém, Pará, Brazil, CEP: 68.010-200.

MICRURUS CLARKI (Clark's Coral Snake). COSTA RICA: Puntarenas: ca 2 km N of Dominical, Hacienda Baru National Wildlife Refuge (09°16'00"N, 83°52'20"W, 10 m elev.). 13 July 2000. M. Ryan. Verified by Federico Bola Hos. Museo de Zoologia de la Universidad de Costa Rica MZUCR 14816 (formerly FB 2562). A juvenile was found dead on the coastal highway in the morning following heavy night rains. Range extension of 85 km and represents the northern limit for this South American species. Previously recorded from the Golfito area of southern Costa Rica.

Submitted by **MASON RYAN**, Department of Zoology, Southern Illinois University, Carbondale, Illinois 62901, USA.

NERODIA ERYTHROGASTER (Plain–bellied Watersnake). USA: ARKANSAS: PERRY CO.: SW1/4, Sec. 3, T3N, R17W. 11 May 2002. Bobby Elliott. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27175). Verified by Stan Trauth. Adult female killed by human. First record for county and fills hiatus between records in Conway and Pulaski counties (Trauth, Robison, and Plummer, ms. in prep.).

Submitted by **KELLY J. IRWIN**, Arkansas Game and Fish Commission, 915 East Sevier Street, Benton, Arkansas 72015, USA; e-mail: kirwin@agfc.state.ar.us.

NINIA ESPINALI (Espinal's Coffee Snake). EL SALVADOR: CHALATENANGO: Cerro El Pital (14°23.3'N, 89°07.0'W), 2270 m elev. 15 May 2001. Roberto Bolaños. KU 291246 and El Salvador National Museum of Natural History (MUHNES C–30–1538). Verified by Gunther Köhler. New records for El Salvador. A recent border change removed the Morazán, El Salvador record (Hidalgo 1981. Herpetol. Rev. 12:67–68) to Honduras (Dueñas et al. 2001. *In* Johnson et al. [eds.], Mesoamerican Herpetology: Systematics, Zoogeography, and Conservation, pp. 93–99. Centennial Museum Special Publ. No. 1, The University of Texas at El Paso, El Paso). The new record is 12 km SSW of the nearest reported locality at Ocotepeque, Honduras (McCranie and Wilson 1995. J. Herpetol. 29:224–232). Both specimens were collected under the same log ca. 5 m from primary cloud forest.

Submitted by **ELI GREENBAUM** and **OLIVER KOMAR**, Division of Herpetology and Division of Ornithology, respectively, Natural History Museum & Biodiversity Research Center, The University of Kansas, 1345 Jayhawk Blvd., Lawrence, Kansas 66045-7561, USA (e-mail: elig@ku.edu and okomar@ku.edu) and **ROBERTO BOLAÑOS**, Col. Miramonte Pte., Pje. El Rosal, Casa No. 24, San Salvador, El Salvador (e-mail: snakeman01_2000@user.kingsnake.com).

STORERIA DEKAYI TEXANA (Texas Brownsnake). USA: TEXAS: MARION CO: 10.0 km N Harleton off FM 1968 at southcentral shore of Lake O' the Pines. 23 September 2002. L. R. Twilley. Arkansas State University Museum of Zoology, Herpetological Collection (ASUMZ 27251). Verified by Stanley E. Trauth. New county record completely filling hiatus along counties bordering eastern part of the state (Dixon 2000. Amphibians and Reptiles of Texas. Texas A&M Univ. Press, College Station. 421 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. of Texas Press, Austin. 437 pp.). Also reported previously from Karnack at nearby Caddo Lake and just east of Harleton in Harrison County, Texas (Hardy 1995. Checklist of the Amphibians and Reptiles of the Caddo Lake Watershed in Texas and Louisiana. Bull. Mus. Life Sci.10:1–31), and adjacent Caddo Parish, Louisiana (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. LSU Press, Baton Rouge. 300 pp.).

Submitted by **CHRIS T. McALLISTER** (e-mail: chris.mcallister@tamut.edu) and **LOMA R. TWILLEY** (e-mail: Lobo7041999@cs.com), Department of Biology, Texas A&M University-Texarkana, Texarkana, Texas 75505, USA.

STORERIA OCCIPITOMACULATA (Red-bellied Snake). USA: ILLINOIS: DEKALB CO: Kirkland. Three specimens were found under old roofing shingle, in a grassy area, ca. 10–15 m from the edge of Owens Creek within the old Boy Scout Camp, Franklin Twp., 88°52'30"N, 42°07'30W, R3E T43N. 10 May 2002. Michael A. Andre. Northern Illinois University HDW-NIU 1927–1929. Verified by Julie Ray and Kristin Stanford. New county record, extending the range from the adjacent eastern Kane and northern McHenry county records (Burbrink and Wilson 1994. Herpetol. Rev. 25:35; Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois, Illinois Nat. Hist. Surv. Manuel [8]:1–282) and southern LaSalle County record (Bittner and Bittner 2001. Herpetol. Rev. 32:280).

Submitted by **MICHAEL A. ANDRE** and **HARLAN D. WALLEY**, Department of Biology, Northern Illinois University, Dekalb, Illinois 60115, USA (e-mail:hdw@niu.edu).

TANTILLA GRACILIS (Flat-headed Snake). USA: LOUISIANA: VERNON PARISH: Fort Polk Military Reservation; 6 km W and 3.2 km N of jct. Hwy 117 and Hwy 465 (31°21'35.2"N, 93°14'10.4"W). 27 March 2002. Beau B. Gregory. Louisiana State University at Eunice Vertebrate Collection (LSUE 730–1). Verified by Jeff Boundy. First Parish record. This record extends the range south from Sabine and Natchitoches Parishes and west from Rapides Parish, as mapped by Dundee and Rossman (1989. The Amphibians and Reptiles of Louisiana, Louisiana St. Univ. Press, Baton Rouge. 300 pp.). Both of these specimens were collected from under the same rock.

Submitted by **AVERY A. WILLIAMS**, Division of Sciences, Louisiana State University at Eunice, Eunice, Louisiana 70535, USA, and **BEAU B. GREGORY**, Environmental and Natural Resource Management Division, Directorate of Public Works, Fort Polk, Louisiana, 71459, USA.

THAMNOPHIS SIRTALIS (Common Gartersnake). USA: LOUISIANA: AVOYELLES PARISH: Hessmer area, Hwy 3041, ca. 7 mi E of Bunkie. 27 June 2000. L. Walls. Louisiana State University at Eunice Vertebrate Collection (LSUE 732). Verified by Jeff Boundy. First Parish record. This record fills the gap between Rapides and Point Coupee Parishes, as mapped by Dundee and Rossman (1989. The Amphibians and Reptiles of Louisiana, Louisiana St. Univ. Press, Baton Rouge. 300 pp.). This specimen was discovered within the house of the collector.

Submitted by **AVERY A. WILLIAMS**, Division of Sciences, Louisiana State University at Eunice, Eunice, Louisiana 70535, USA.

THAMNOPHIS VALIDUS VALIDUS (Pacific Gartersnake). MÉXICO: CHIHUAHUA: Río Batopilas (27°1'37.3"N, 107°44'20.4"W), 550 m elev. 18 June 2001. Herpetological Collection of Unidad de Biología, Tecnológico y Prototipos (UBIPRO 7332). Verified by Richard L. Holland. First record from Chihuahua and ca. 75 km range extension SE of Alamos, Sonora (Conant 1969. Bull. Am. Mus. Nat. Hist. 142:1–140).

Submitted by **JULIO A. LEMOS-ESPINAL**, under CONABIO project U003, Laboratorio de Ecología, IBIPRO, Facultad de Estudios Superiores Iztacala, UNAM, Tlalnepantla, Estado de México, 54090 México (e-mail: lemos@servidor.unam.mx); **DAVID L. New County Records of Amphibians and Reptiles from West-Central Illinois

JOHN A. CRAWFORD
Division of Biological Sciences, University of Missouri
105 Tucker Hall, Columbia, Missouri 65211, USA
e-mail: jac7vc@mizzou.edu

and

MATHYS J. MEYER
Department of Biological Sciences, Illinois State University
Normal, Illinois 61790-4120, USA
e-mail: altboer@hotmail.com

Surveys of the herpetofauna of Illinois have become quite common over the past few years in an effort to determine species ranges and develop management plans (Markezich and Beckett 2001; Petzing et al. 1998; Petzing et al. 2000; Redmer and Ballard 1995; Wilson 1999). Although many sites throughout Illinois have been well sampled, several areas remain unstudied (Markezich and Beckett 2001). The 14 new county records presented are the result of field work conducted in west central Illinois where amphibian and reptile presence and species composition are poorly documented. Unless otherwise noted, specimens were verified by Christopher A. Phillips and deposited in the herpetological collection at the Illinois Natural History Survey (INHS). County records were verified by consulting published distributions in Phillips et al. (1999) and the Illinois Herpetological Database maintained by the Illinois Natural History Survey. The Illinois Herpetological Database contains information on Illinois amphibian and reptile species from 30 U.S. collections and can be accessed at the following URL:

http://www.inhs.uiuc.edu/cbd/herpdist/herp.html

Anura

Bufo fowleri (Fowler's Toad). Stark Co: Along 1500 N, just W of 935 E. 14 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17452. New county record. Two newly metamorphosed toadlets (catalogued under the same museum number) collected along a roadside ditch.

Hyla chrysoscelis/Hyla versicolor (Gray Treefrog Complex). Knox Co: Green Oaks Biological Field Station. 13 June 2001. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. INHS 17354. New county record. One male collected from a chorus at Gate Pond. Stark Co: Along 1500 N, just W of 935 E. 13 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17355. New county record. One male collected from a small chorus in a roadside ditch.

Pseudacris triseriata (Western Chorus Frog). Stark Co: 0.1 mi S of 1100 N, 0.8 mi east of 950 E. 4 April 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17234. New county record. One male collected from a chorus in a small farm pond.

Rana blairi (Plains Leopard Frog). Stark Co: Along 1500 N, just W of 935 E. 13 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17356. New county record. Collected in a roadside ditch.

Rana clamitans (Green Frog). Stark Co: On 1200 E, 3.1 mi N of 1425 N. 13 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17357. New county record. AOR adult.

Testudines

Chelydra serpentina (Snapping Turtle). Knox Co: Green Oaks Biological Field Station. 15 June 2001. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. INHS 2002.02–2002.03 (photo vouchers). New county record. Two adult specimens were trapped, photographed, and released at Little John Trail Pond.

Chrysemys picta (Painted Turtle). Knox Co: Green Oaks Biological Field Station. 19 April 2001. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. INHS 17240. New county record. Dead adult found in Little John Trail Pond.

Trachemys scripta (Pond Slider). Knox Co: Snakeden Hollow State Fish and Wildlife Area. 14 June 2001. M. J. Meyer and J. A. Crawford. Verified by R. Kniseley. New county record. Shell housed at the field office of Snakeden Hollow State Fish and Wildlife Area.

Serpentes

Coluber constrictor (Eastern Racer). Knox Co: On 1800 E, 1.7 mi S of Victoria. 13 June 2001. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. INHS 17421. New county record. DOR adult. Stark Co: On 1120 N, 0.3 mi W of 1175 E. 15 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. New county record. DOR adult.

Elaphe vulpina (Western Foxsnake). PEORIA CO: On IL Rte 150, 0.2 mi N of Illinois Rte 78 junction. 15 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17361. New county record. DOR adult.

Lampropeltis triangulum (Milk Snake). KNOX CO: On 1700 N (Snake Den Road), 0.9 mi W of 1950 E. 14 June 2001. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. INHS 17360. New county record. AOR adult.

Storeria dekayi (DeKay's Brown Snake). STARK CO: On 1425 N, 0.1 mi W of 1200 E. 13 June 2001. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 17417. New county record. DOR adult.

Acknowledgments.—We thank Stuart Allison and Joe Deviney for granting us access to the biological field station at Green Oaks, and Rick Kniseley for permitting us to use the Snakeden Hollow State Fish and Wildlife Area. We are grateful to Christopher A. Phillips and John E. Petzing of the Illinois Natural History Survey for verifying specimen identifications and providing various data. We thank Andrew R. Kuhns and Jarrett R. Johnson for critically reading the manuscript. We also thank the Illinois Wildlife Preservation Fund of the Illinois Department of Natural Resources, Division of Natural Heritage for grants 01-058W (to JAC) and 01-046W (to MJM) that partially supported this field work. Lastly, MJM would like to thank the Illinois Chapter of the Wild Turkey Federation for monetary assistance. Specimens were collected under Illinois Department of Natural Resources permit numbers A01.0205 (JAC), A01.0162 (MJM), and IDNR Division of Natural Heritage Special Permit for Snakeden Hollow State Fish and Wildlife Area (MJM).

This article is a continuation of recent contributions published in *Herpetological Review* focusing on new amphibian and reptile county records in Illinois. Recent articles include Petzing et al. (1998, 2000), Wilson (1999), and Markezich and Beckett (2001). Specimens reported herein are housed in the Illinois Natural History Survey (INHS) and Southern Illinois University at Carbondale herpetological collections. County records were verified by checking the Illinois Herpetological Database, located at the Illinois Natural History Survey, which contains data on Illinois amphibians and reptiles from 30 museum and private collections and unvouchered records from herpetologists and other reliable biologists. Using information from the database, a web page was developed to provide county-level distribution data for amphibians and reptiles in Illinois. This web site can be accessed at:

http://www.inhs.uiuc.edu/cbd/herpdist/herp.html

The database can be searched by either species or county and distribution maps or county species lists may be printed out for field reference.

Caudata

Ambystoma maculatum (Spotted Salamander). PERRY CO: 5.7 km SW Pinckneyville (NW 1/4 Sec. 4, T6S, R3W; NAD 83 UTM Zone 16: N4212648m, E285781m). 14 March 2000. J. M. Mui, J. E. Petzing, and M. J. Dreslik. Verified by C. A. Phillips. INHS 15697. New county record. Adult found under log near ephemeral pond.

Ambystoma tigrinum (Tiger Salamander). SALINE CO: 6.6 km NW of Carrier Mills, N of new Illinois Rt. 13 alignment and 1 km E of Williamson Co./Saline Co. line (SE 1/4 Sec. 18, T9S, R5E; NAD 83 UTM Zone 16: N4177846m, E350574m). 27 April 2001. J. E. Petzing, J. M. Mui, and J. A. Koontz. Verified by C. A. Phillips. INHS 17144. New county record. Larva collected in emergent wetland.

Hemidactylium scutatum (Four-toed Salamander). CARROLL CO: 1.3 km W jct. Ridge Rd. and West Camp Creek Rd. (NW 1/4 SW 1/4 Sec. 4, T25N, R3E; NAD 83 UTM Zone 15: N4674659m, E733578m). 19 April 2001. C. A. Phillips and W. C. Handel. Verified by J. E. Petzing. INHS 17130. New county record. Adult found under log near intermittent stream.

Plethodon glutinosus (Northern Slimy Salamander). EDGAR CO: 3.5 km SSE of Logan, N side of Brouilletts Creek (NE 1/4 Sec. 35, T15N, R11W). 19 October 2000. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 16874. New county record. Single specimen.

Necturus maculosus maculosus (Common Mudpuppy). EDGAR CO: NNE of Clays Prairie in Brouilletts Creek (NW 1/4 Sec. 32, T15N, R10W). 15 April 2000. J. A. Crawford and C. G. Gutmann. Verified by C. A. Phillips. INHS 16875. New county record. Single specimen.

Anura

Bufo americanus (American Toad). STARK CO: 3 km W of Bradford, East Fork Spoon River at Co. Rd. 1400N (NAD 83 UTM Zone 16: N4561942m, E273253m). 1 April 2000. J. A. Crawford, C. G. Gutmann, and M. J. Meyer. Verified by C. A. Phillips. INHS 16872. New county record. Single specimen.

Hyla chrysoscelis/Hyla versicolor (Gray Treefrog Complex). Dewitt Co: 7.7 km NNE of Maroa, gravel pit S of Weldon Springs State Park and S of Salt Creek (NE 1/4 NE 1/4 Sec. 13, T19N, R2E; NAD 83 UTM Zone 16: N4441691m, E336217m). 11 July 2000. C. A. Phillips, E. E. Conrad, J. M. Mui, and J. R. Jakubanis. Verified by J. E. Petzing. INHS 15854. New county record. Adult male; MOULTRIE CO: 0.7 km N of Allenville; 0.2 km N of Co. Rd. 1100N and 0.45 km W of Illinois Rt. 121 (SE 1/4 SW 1/4 SE 1/4 Sec. 16, T13N, R6E; NAD 83 UTM Zone 16: N4380686m, E368295m). 19 July 2000. J. M. Mui, E. E. Conrad, T. Griffith, and J. R. Jakubanis. Verified by C. A. Phillips. INHS 15870. New county record. Adult male.

Pseudacris crucifer (Spring Peeper). CLARK CO: E of Patton, S of Co. Rd. 2250N and W of State Line Rd. (NW 1/4 Sec. 21, T12N, R10W; UTM Zone 16: N4369869m, E454220m). 24 February 2001. C. A. Phillips, J. M. Mui, D. B. Shepard, B. C. Jellen, A. R. Kuhns, and M. J. Dreslik. Verified by J. E. Petzing. INHS 16951. New county record. Adult collected from ephemeral pond; JOHNSON CO: 3.14 km S of Main St. in Belknap on Karnak Rd. (NW 1/4 NW 1/4 NW 1/4 Sec. 14, T14S, R2E). 16 March 2000. J. G. Palis. Verified by J. Stewart. SIUC H-6598. New county record. AOR adult male on Karnak Rd. at 0237 h.

Pseudacris triseriata (Western Chorus Frog). GRUNDY CO: 1.4 km SSE of Morris (SW 1/4 Sec. 11, T33N, R7E; NAD 83 UTM Zone 16: N4578550m, E383080m). 6 April 2000. J. E. Petzing and J. M. Mui. Verified by C. A. Phillips. INHS 15705. New county record. Adult under log in dry ephemeral wetland basin east of the Mazon River; KNOX CO: NE of Co. Rt. 5 (DeLong Blacktop), W of DeLong at Brush Creek (Sec. 30, T10N, R1E). 24 April 2000. T. G. Anton. Verified by C. A. Phillips. INHS 16829. New county record. Another specimen (INHS 16871) was collected at Knox College Green Oaks Field Station on 20 April 2000 by M. J. Meyer and J. A. Crawford; PUTNAM CO: 0.8 km SSE of Moronts, tributary Allforks Creek N of New York Central RR/Chicago, Milwaukee, St. Paul and Pacific RR trestle (SW 1/4 SW 1/4 SE 1/4 Sec. 36, T33N, R2W; NAD 83 UTM Zone 16: N4572331m, E308291m). 19 October 2000. J. E. Petzing, J. M. Mui, A. R. Kuhns, D.B. Shepard, and M. J. Dreslik. Verified by C. A. Phillips. INHS 16450. New county record. Adult collected under slab rock in dry creek bed.

Rana areolata circulosa (Northern Crawfish Frog). JOHNSON CO: 1.37 km N of Main St. in Belknap on Belknap Rd. (SW 1/4 NW 1/4 NW 1/4 Sec. 6, T14S, R3E). 18 May 2000. J. G. Palis. Verified by J. Stewart. SIUC H-6599. New county record. AOR adult male on Belknap Rd. at 2218 h.

Rana blairi (Plains Leopard Frog). HANCOCK CO: 2.2 km S of Elvaston, West Fork Bear Creek at Co. Rd. 1300E (NE 1/4 Sec. 1, T4N, R8W; NAD 83 UTM Zone 16: N4477475m, E138770m). 1 May 2001. M. E. Retzer and R. S. Steinberg. Verified by C.A. Phillips. INHS 17159. New county record. Single specimen; KNOX CO: Snakeden Hollow State Fish and Wildlife Area. 20 April 2000. M. J. Meyer and J. A. Crawford. Verified by C. A. Phillips. INHS 16870. New county record. Gravid female.

Rana catesbeiana (American Bullfrog). MENARD CO: Rock Creek at Illinois Rt. 97 (SE 1/4 Sec. 13, T17N, R7W; NAD 83 UTM Zone 16: N4422642m, E257264m). 26 April 2000. C. A. Phillips. Verified by J. E. Petzing. INHS 15717. New county record. Single specimen; STARK CO: 3 km W of Bradford, East Fork Spoon River at Co. Rd. 1400N (NAD 83 UTM Zone 16: N4561942m, E273253m). 1 April 2000. J. A. Crawford, C. G. Gutmann, and M. J. Meyer. Verified by C. A. Phillips. INHS 16873. New county record. Tadpole.

Rana clamitans (Green Frog). BUREAU CO: 4.75 km W of Hennepin (NE 1/4 NW 1/4 Sec. 25, T15N, R9E; NAD 83 UTM Zone 16: N4570496m, E298623m). 23 June 2000. J. E. Petzing and W. C. Handel. Verified by C. A. Phillips. INHS 15788. New county record. Adult collected from water-filled depressions in seep area near a gravel pit; CRAWFORD CO: 5.1 km WNW of Birds; 0.3 km N Co. Rd. 000N on Co. Rd. 1150E (NW 1/4 SW 1/4 SE 1/4 Sec. 22, T5N, R12W). 25 October 2000. D. B. Shepard, M. J. Dreslik, J. E. Petzing, and J. M. Mui. Verified by C. A. Phillips. INHS 16480. New county record. Collected from small, wooded pond on the east side of Co. Rd. 1150E. Single specimen; PEORIA CO: NNE of North Hampton; 0.4 km E of Senachwine Creek (NE 1/4 Sec. 13, T11N, R8E; NAD 83 UTM Zone 16: N4535400m, E287061m). 11 May 2000. J. E. Petzing, J. M. Mui, and M. J. Dreslik. Verified by C. A. Phillips. INHS 15730. New county record. Collected from forested pond. Single specimen.

Rana sphenocephala (Southern Leopard Frog). CRAWFORD CO: ditch E of Honey Creek and N of Co. Rd. 600N (SE 1/4 SE 1/4 SW 1/4 Sec. 20, T6N, R12W; NAD 83 UTM Zone 16: N4310035m, E433398m). 2 November 2000. M. J. Dreslik, J. E.

Petzing, D. B. Shepard, and J. M. Mui. Verified by C. A. Phillips. INHS 16526. New county record. Adult.

Testudines

Chrysemys picta (Painted Turtle). SHELBY CO: 1.6 km N of Effingham Co. line on Interstate 57. 3 June 1969. E. O. Moll. Verified by C. A. Phillips. INHS 15437. New county record. Male.

Emydoidea blandingii (Blanding's Turtle). IROQUOIS CO: Iroquois County Conservation Area. June 1979. E.O. Moll. Verified by C. A. Phillips. INHS 15641. New county record. Hatchling.

Trachemys scripta elegans (Red-eared Slider). LASALLE CO: 0.3 km W of creek on CSX RR tracks; 1.6 km W of Blackball Mine. 29 August 2000. T. G. Anton and D. Mauger. Verified by C. A. Phillips. INHS 16425. New county record. Single specimen; WHITE CO: 9.7 km E Carmi, Browns Pond Ditch at Co. Rd. 1800E (SE 1/4 Sec. 13, T5S, R10E; NAD 83 UTM Zone 16: N4215352m, E408605m). 31 October 1999. L. M. Page and M. H. Sabaj. Verified by C. A. Phillips. INHS 15749. New county record. Single specimen.

Sternotherus odoratus (Stinkpot). JOHNSON CO: 3.4 km S of Main St. in Belknap on Karnak Rd. (NE 1/4 NE 1/4 Sec. 15, T14S, R2E). 22 June 2000. J. G. Palis. Verified by J. Stewart. SIUC R-3802. New county record. DOR juvenile on Karnak Rd. at 1724 h.

Apalone spinifera (Spiny Softshell). MARION CO: Kaskaskia River near Centralia. 13 October 1970. E.O. Moll. Verified by C. A. Phillips. INHS 17202. New county record. Skull and partial skeleton of an adult.

Lacertilia

Eumeces laticeps (Broad-headed Skink). WHITE CO: 5.5 km WNW of Crossville on Hanks Ferry Bridge above the Little Wabash River (SE 1/4 SE 1/4 SE 1/4 Sec. 33, T3S, R10E; NAD 83 UTM Zone 16: N4230031m, E404109m). 21 July 2000. M. J. Dreslik, J. M. Mui, and J. E. Petzing. Verified by C. A. Phillips. INHS 15874. New county record. Juvenile collected on old bridge.

Cnemidophorus sexlineatus (Six-lined Racerunner). PUTNAM CO: 0.8 km SSE of Moronts, New York Central RR/Chicago, Milwaukee, St. Paul and Pacific RR at tributary Allforks Creek (SW 1/4 SW 1/4 SE 1/4 Sec. 36, T33N, R2W; NAD 83 UTM Zone 16: N4572265m, E308295m). 19 October 2000. J. E. Petzing, A. R. Kuhns, D. B. Shepard, J. M. Mui, and M. J. Dreslik. Verified by C. A. Phillips. INHS 16456. New county record. Juvenile collected along RR tracks just east of the trestle over Allforks Creek.

Serpentes

Coluber constrictor (Eastern Racer). LAWRENCE CO: 0.6 km S of mile marker 3 on Illinois Rt. 33, S of Russellville. 24 October 2000. A. R. Kuhns. Verified by C. A. Phillips. INHS 16496. New county record. DOR adult.

Diadophis punctatus (Ring-necked Snake). EDGAR CO: 3.5 km SSE of Logan, N side Brouilletts Creek (NE 1/4 Sec. 35, T15N, R11W). 8 April 2000. J. A. Crawford, M. J. Meyer, and C. G. Gutmann. Verified by C. A. Phillips. INHS 16876. New county record; JO DAVIESS CO: 3.2 km NW jct. Blackjack Rd. and West Beaty Hollow Rd., Witkowski Fish and Wildlife Area (SW 1/4 Sec. 26, T27N, R1E; NAD 83 UTM Zone 15: N4686951m, E717654m). 19 April 2001. C. A. Phillips and W. C. Handel. Verified by J. E. Petzing. INHS 17156. New county record. Male.

Elaphe spiloides (Central Ratsnake). MARSHALL CO: N of Hopewell, Illinois Rt. 29 at Rattlesnake Hollow (Sec. 26, T12N, R9E; NAD 83 UTM Zone 16: N4540549m, E294253m). 29 August 2000. T. G. Anton and D. Mauger. Verified by C. A. Phillips. INHS 16828. New county record. DOR. Single specimen.

Elaphe vulpina (Western Foxsnake). PUTNAM CO.: 0.8 km SSE of Moronts, New York Central RR/Chicago, Milwaukee, St. Paul and Pacific RR at tributary Allforks Creek (SW 1/4 SW 1/4 SE 1/4 Sec. 36, T33N, R2W; NAD 83 UTM Zone 16: N4572077m, E308278m). 19 October 2000. D. B. Shepard, A. R. Kuhns, J. E. Petzing, J. M. Mui, and M. J. Dreslik. Verified by C. A. Phillips. INHS 16482. New county record. Single specimen collected under piece of sheet metal at base of RR trestle.

Heterodon platirhinos (Eastern Hog-nosed Snake). EDGAR CO: 2 km W of Saint Bernice, S of Co. Rd. 700N (NW 1/4 NE 1/4 Sec. 32, T15N, R10W). 15 April 2000. J. A. Crawford and C. G. Gutmann. Verified by C. A. Phillips. INHS 16877. New county record. Adult; PEORIA CO: NNE of North Hampton, E side of Senachwine Creek (NE 1/4 Sec. 13, T11N, R8E; NAD 83 UTM Zone 16: N4535224m, E287192m). 11 May 2000. J. E. Petzing, J. M. Mui, and M. J. Dreslik. Verified by C. A. Phillips. INHS 15733. New county record. Juvenile found in floodplain forest/upland forest interface.

Lampropeltis calligaster calligaster (Prairie Kingsnake). LAWRENCE CO: 0.72 km S of Birds–Chauncey Rd. on Illinois Rt. 1 (NW 1/4 NW 1/4 NW 1/4 SW 1/4 Sec. 31, T5N, R11W). 25 October 2000. D. B. Shepard, M. J. Dreslik, J. M. Mui, and J. E. Petzing. Verified by C. A. Phillips. INHS 16488. New county record. DOR adult on east shoulder of Illinois Rt. 1.

Lampropeltis triangulum triangulum (Eastern Milksnake). PUTNAM CO: 0.8 km SSE of Moronts, New York Central RR/Chicago, Milwaukee, St. Paul and Pacific RR at tributary Allforks Creek (SW 1/4 SW 1/4 SE 1/4 Sec. 36, T33N, R2W; NAD 83 UTM Zone 16: N4572291m, E308263m). 19 October 2000. A. R. Kuhns, J. E. Petzing, J. M. Mui, D. B. Shepard, and M. J. Dreslik. Verified by C. A. Phillips. INHS 16742. New county record. Single specimen found under old RR tie along embankment.

Opheodrys aestivus (Rough Greensnake). SHELBY CO: 8.45 km ESE Oconee at Becks Creek. 19 September 2000. M. E. Retzer. Verified by C. A. Phillips. INHS 16975. New county record. DOR adult.

Pituophis catenifer sayi (Bullsnake). SCOTT CO: 3.7 km SSW of Oxville on Illinois Rt. 100 (SW 1/4 Sec. 8, T14N, R13W). 29 April 2001. M. E. Retzer. Verified by C. A. Phillips. 17155. New county record. DOR adult.

Storeria dekayi wrightorum (Midland Brownsnake). LAWRENCE CO: 1.5 km S of Chauncey, The Slough at Co. Rd. 200E (Sec. 4, T4N, R13W; NAD 83 UTM Zone 16: N4296822m, E424424m). 2 November 2000. M. J. Dreslik, J. M. Mui, J. E. Petzing, and D. B. Shepard. Verified by C. A. Phillips. INHS 16514. New county record. AOR juvenile; MARION CO: N of Omega at Stephen A. Forbes State Park, W of Lost Fork (NW 1/4 SE 1/4 Sec. 32, T4N, R4E). 16 May 2001. R. Phillippe and D. Ketzner. Verified by C. A. Phillips. INHS 17203. New county record. Adult found dead

with crushed head; PUTNAM Co: 1.5 km SW of McNabb (SW 1/4 SW 1/4 SW 1/4 NE 1/4 Sec.9, T31N, R1W). 19 October 2000. J. E. Petzing, A. R. Kuhns, D. B. Shepard, M. J. Dreslik and J. M. Mui. Verified by C. A. Phillips. INHS 16457. New county record. DOR adult; SANGAMON Co: 5.6 km ENE of Pleasant Plains. 22 October 2000. R. Mosher. Verified by C. A. Phillips. INHS 16864. New county record. DOR adult; SCOTT Co: 0.56 km W of Co. Rd. 1600E on Co. Rd. 500N; 6.1 km NW of Manchester (SE 1/4 Sec. 6, T13N, R11W). 5 April 2001. J. E. Petzing, J. M. Mui, and M. J. Dreslik. Verified by C. A. Phillips. INHS 17098. New county record. Single specimen; SHELBY Co: 4.3 km N of Beecher City, Co. Rd. 100N just W of Co. Rd. 1900E (NE 1/4 NE 1/4 NE 1/4 NE 1/4 Sec. 18, T9N, R4E; NAD 83 UTM Zone 16: N4343893m, E345738m). 22 October 2000. J. E. Petzing. Verified by C. A. Phillips. INHS 16461. New county record. AOR. Single specimen.

Thamnophis proximus (Western Ribbonsnake). PERRY Co: 0.3 km S of Illinois Rt. 154 in Beaucoup Creek, E of Pinckneyville (NW 1/4 Sec. 19, T5S, R2W; NAD 83 UTM Zone 16: N4217116m, E292419m). 26 April 2001. J. E. Petzing, J. M. Mui, and J. A. Koontz. Verified by C. A. Phillips. INHS 17157. New county record. Adult collected in Beaucoup Creek.

Thamnophis sirtalis sirtalis (Eastern Gartersnake). CRAWFORD Co: 2.1 km S of Co. Rd. 550N on Co. Rd. 400E (SE 1/4 Sec. 32, T6N, R13W; NAD 83 UTM Zone 16: N4307408m, E424581m). 24 October 2000. A. R. Kuhns. Verified by C. A. Phillips. INHS 16504. New county record. Single specimen; Stark Co: 1.5 km N of Wyoming, 0.8 km E of Co. Rd. 1050E on Co. Rd. 800N (NAD 83 UTM Zone 16: N4552511m, E267096m). 20 April 2000. J. A. Crawford and M. J. Meyer. Verified by C. A. Phillips. INHS 16878. New county record. Adult male.

Acknowledgments.—We thank Kevin Cummings and Chris Taylor for reviewing the manuscript. Field work by JEP, JMM, MJD, and CAP was partially supported by a contract with the Illinois Department of Transportation. Additional field work by JEP was partially supported by a grant from the Wildlife Preservation Fund (Illinois Department of Natural Resources, Division of Natural Heritage). Field work by JAC was partially supported by a grant from the Wildlife Preservation Fund (Illinois Department of Natural Resources, Division of Natural Heritage). Field work by MJM was partially supported by a grant from the Wildlife Preservation Fund (Illinois Department of Natural Resources, Division of Natural Heritage), and a scholarship from the Illinois Chapter of the Wild Turkey Federation. A special thanks goes to M. F. Dreslik and E. Dreslik from MJD, JEP, JMM, and DBS for the use of their van during two collecting trips to Crawford and Lawrence counties.

There are several books that deal specifically with aspects of the biology of sea snakes worldwide (e.g., Dunson 1975; Heatwole 1999). No one region of the world, however, has been the focus of a book length treatment of sea snakes before. New Caledonia, with 14 species of sea snakes, is relatively rich in these reptiles, including several regionally endemic forms (e.g., *Hydrophis coggeri*, *H. laboutei*), a few probable vagrants (*H. spiralis*, *Lapemis curtus*), the widely distributed pelagic species *Pelamis platurus*, and numerous species with chiefly Australian or Asian distributions that reach their easternmost range limits in New Caledonian waters.

Despite its focus on New Caledonia, this volume provides a useful introduction to sea snakes as a whole and, with more than 135 color photos, it is certainly the most well-illustrated book on marine elapids to date. Further, with its bilingual text (English and French on facing pages), the book is accessible to a broad spectrum of readers.

An introductory overview of sea snakes (pp. 15–50) discusses 16 different topics including diversity, phylogeny, feeding, reproduction, mimicry, parasitism, diving, and conservation. This is an excellent and up-to-date review of sea snake biology that will be informative for professional herpetologists and yet still fully comprehensible to a non-technical audience. Thirty-six footnotes explain terms or concepts that may be unfamiliar to some readers (e.g., proteroglyphic teeth, monotypic, fouling organisms). The only term that struck me as requiring, but lacking, such a footnote was "nycthemeral" (p. 86).

Like the book as a whole, the introduction is illustrated by numerous color photos of sea snakes, their habitats, predators and

prey. These are mostly the work of Pierre Laboute, who has spent years observing and photographing sea snakes in New Caledonia. While nearly all of the photos are excellent, perhaps the most intriguing illustrates a juvenile *Emydocephalus annulatus* captured by a sea anemone—the first documentation of this particular cross-phylum predation.

The bulk of the book (pp. 51–264) deals specifically with the sea snakes of New Caledonia. This section begins with a series of color maps, illustrating the areas (chiefly near Nouméa) where Laboute's observations were made. This is followed by a short overview of the history of sea snake studies in New Caledonian waters, a discussion of the morphological features important for the identification of sea snakes, and a key to the 14 species reported from New Caledonia. These sections are well-illustrated by both line drawings and diagnostic photos of selected features. The species accounts themselves include Latin and common names, an introductory paragraph about each species and its biology, and more detailed information under the headings: taxonomy, description, coloration, body size, sexual dimorphism, geographic distribution, habitat and ecology, feeding, reproduction, predators, venom and snake bite, and the status of populations in New Caledonia. All accounts are also accompanied by a shaded distribution map.

Each account discusses the species as a whole, but emphasizes what is known about the variation and/or biology of the snake in New Caledonia. For example, the account of *Hydrophis ornatus* is full of useful information about the morphology of the local population, based on material in the Muséum National d'Histoire Naturelle in Paris. Much of the biological data is derived from Laboute's personal experience around the reefs and islets of the New Caledonian lagoon and represents previously unpublished information. In particular, welcome new observations regarding diet, reproduction, and depth and time of activity are described. These are sometimes presented in a summarized form in the main text, but elsewhere appear in the form of direct quotes describing behaviors seen on particular dives.

Not surprisingly the length of each account, as well as the number and variety (although not the quality) of illustrations, is highly variable. The sea kraits (*Laticauda*), by far the most commonly encountered sea snakes in the region, are the most terrestrial of all sea snakes and have been the subject of much research, most notably the detailed study in New Caledonia by Saint Girons (1964). As a consequence, the text for *L. colubrina* extends over 28 pp (70–97) and includes 13 photos. Other accounts range from eight pages for *Hydrophis laboutei* (newly described in 2000 and known from only two specimens) to 18 pages for the more abundant and well known *Acalyptophis peroni* and *Aipysurus laevis*. All of the accounts are well-illustrated and only those *H. laboutei*, *H. spiralis*, and *Lapemis curtus* (the latter two species are each known from only one New Caledonian specimen) lack photos of living animals from the New Caledonian region. Among the most biologically interesting photographs are those of freshly laid *Laticauda laticuadata* eggs (p. 109), foraging by several species (including one of a swimming *Acalyptophis peroni* with a fish in its mouth; p. 123), and courtship of *Aipysurus laevis* (p. 150).

The last full chapter is one on venom, snake bite, and envenomation. Thankfully, there are only two known fatalities from sea snake bites in New Caledonia, but data gathered from clinical cases as well as experimental studies, both in New Caledonia and elsewhere, permit a reasonably detailed picture of sea snake toxinology to be presented. There is a widespread belief in New Caledonia that sea snakes in general are not dangerous. While this is true of *Emydocephalus annulatus*, which feeds on fish eggs, all of the remaining species, even if not aggressive, are potentially hazardous to humans. Ineich and Laboute review the risk from sea snakes, provide information about symptoms and both first aid and hospital treatment. They also cross reference several websites that provide current information on the treatment of sea snake bites.

The book concludes with a literature cited section of 101 references, three appendices (New Caledonian sea snake abundance—based on individual dives by Pierre Laboute, relative abundance of New Caledonian sea snakes in the Muséum National d'Histoire Naturelle collection, and sea snake distribution within the New Caledonian region—New Caledonia, Loyalty Islands and Chesterfield Reefs), and a (primarily taxonomic) index.

Laboute's photographs alone are worth the price of the book. Sea snakes are notoriously difficult to photograph (or at least photograph well). Many published photos (excluding those of the semi-terrestrial sea kraits) show preserved animals or those recently removed from trawler nets. In contrast, Laboute's photos give a real sense of sea snakes as living organisms and add substantially to the reader's appreciation of their biology.

I noted only a few minor problems in the book. In a very few places the English is somewhat awkward (e.g., caption, p. 20; caption, p. 88; text, p. 268) or misspellings occur (e.g., "mangoose" instead of "mongoose" on p. 94). In only one instance is the English translation potentially misleading (p. 36; "bandes," correctly translated as bands or rings elsewhere, is here translated as stripes). In general the English translation follows the French text quite precisely, and both are well written. With regard to the illustrative material, one photo, that of a foraging *Emydocephalus* (p. 168), is printed upside down and one map (Figure 1) needs a minor correction. The map illustrates the range of *Pelamis platurus* as including the waters around the whole of the North Island of New Zealand (where this species, as well as *Laticauda colubrina*, occasionally occurs as a vagrant; Gill 1997), but does not include the south coast of South Africa or the central Namibian coast, where the species is also a rare vagrant (Branch 1998). Finally, one might take issue with the over-generous margins; on pages without photos, the text occupies only 27–36% of the page area!

Sea Snakes of New Caledonia is a valuable contribution to the study of both sea snakes and Pacific herpetology. It should be on the shelves of herpetologists with interests in either topic, as well as those of marine biologists and divers. I also recommend it highly to anyone who appreciates good snake photography.

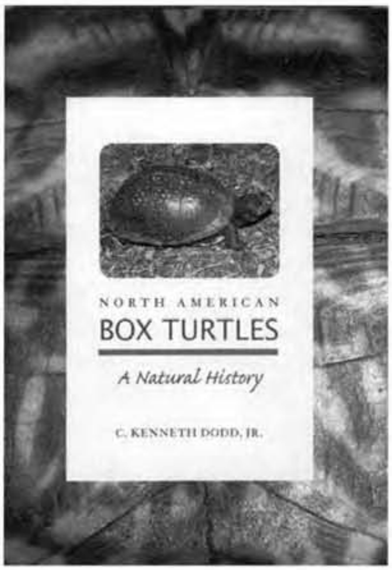
e-mail: Jeffrey_lovich@usgs.gov

I am like many herpetologists that were born in the eastern United States: my introduction to our chosen field began with a box turtle. My father picked up a colorful specimen crossing the road in Prince George's County, Maryland, not far from our home in Alexandria, Virginia. He brought it home, thus launching my career in herpetology when I was only six years old. Ken Dodd, who was also raised in northern Virginia box turtle country, has successfully captured the allure of the engaging box turtle in this landmark book: surprisingly, the first comprehensive treatment of the wide-ranging and ever-popular *Terrapene carolina* and its relatives.



The book is nicely divided into two parts. The first covers the biology, life history and conservation of box turtles in an engaging style that will appeal to both professionals and lay people alike. The second part focuses on more technical details related to systematic accounts of each species. Chapters include an Introduction to the Box Turtle; The Evolution of Box Turtles; Habitats and Habitat Requirements; Activity, Movements and Orientation; Behavior and Senses; Courtship and Reproduction; Food and Feeding Behavior; Population Structure and Demography; Predators, Parasites and Disease; Conservation Biology; species accounts for *Terrapene carolina*, *T. coahuila*, *T. nelsoni*, and *T. ornata*; a Glossary, and an extensive Literature Cited. The book is well illustrated with graphs and photographs, but the photographs are rather small, and some are of poor quality.

One of the real strengths of the book is the concluding section in each of the chapters on natural history where Dodd examines gaps in our knowledge of box turtles and proposes questions for future research. Again, for such visible and widespread species, it is amazing how much we don't know about box turtles, especially the Mexican forms. Graduate students and scientists who are interested in box turtles will find a wealth of ideas for fruitful study in Dodd's recommendations for future research.

The book is very readable and Dodd's interest and passion for his study animal is conveyed throughout. At times, that passion turns to editorializing about the species as a whole based on his research experience at Egmont Key, off the west coast of Florida. As Dodd states in his Preface, "Much of the basis for this book rests on the shells of Egmont's box turtles." It is not unusual for scientists who have studied an organism at one site for several years to consider their population representative of the species or group as a whole. This is rarely true, however, as a single population represents only one set of ecologic and demographic parameters during a relative short period of study. If the reader keeps that caveat in mind, the editorializing is a minor detraction.

It is difficult to write a book that appeals to both a professional and a non-scientific audience, as Dodd admits in the Preface to the book. He then offers a quote from Henry Pilsbry: "If you want to learn how much you can overlook or forget, just write a book." Despite this prophecy, Dodd managed to write a book that will appeal to both audiences. It is in the spirit of the Pilsbry quote and constructive criticism that I offer the remainder of this review.

While the author states in the Preface that the bibliography is not exhaustive with respect to popular turtle books, especially those on captive care, several important scientific papers are also missing from the discussions, or not cited in strategic locations. For example, the discussion of North American versus Asian box turtles does not cite Bramble (1974) on differences in shell closure morphology, although the presence of that citation in the literature cited presumes that it occurs elsewhere in the book. In the section on Senses, the author cites the classic paper by Yerkes (1904) in discussing the aversion of some turtles to the visual cue of a cliff. However, he fails to cite more recent papers by Ashe et al. (1975) and Patterson (1971) that present data on *T. coahuila* and *T. carolina*, respectively.

In the section on coping with the environment, no mention is made of the findings of Ernst (1968) regarding evaporative water loss in *Terrapene*. While other dissertations are cited, the winter thermal ecology and movement data of Boucher (1999) are missing. Helminth parasite references are given, but the reference by Ernst and Ernst (1979) on protozoans is missing. In addition, important papers by Bels et al. (1992) and Summers et al. (1998) on the kinematics of aquatic and terrestrial prey ingestion are not discussed. Additional missing papers are cited in Ernst and McBreen (1991a, b) and Ernst et al. (1994).

Some of the figures are confusing or in error. For example, Figure 4.4, presenting temperature data from Egmont Key, appears to be flawed as the graphed and printed ranges do not match one another. Similarly, Figures 4.5 and 4.6 have captions suggesting that the means for each category are the same as their standard deviations in 7 out of 7 cases.

Despite the normal minor errors of omission and commission expected in a major tome, a book like this has been long overdue and herpetologists and natural historians alike owe a debt of grati-

tude to Dodd for compiling such a critical mass of information. I am struck by how even formerly common and "well-known" taxa like box turtles go for so long without a systematic synthesis of the state of our scientific knowledge. If you are a serious student of turtles or a lover of natural history classics, then this is a book that you must have and read.

One of my most prized possessions is an original copy of this reprinted classic, purchased directly from Oxford University Press for 30 Shillings (then about $6.60) during my first year of graduate studies. It has been extremely well used, not only by me but by 35+ years of students who have repeatedly xeroxed parts of it. Amazingly, it is still in great shape, although its paper wrapper is in tatters and consists as much of tape as paper. The reason for the care with which it has been used is that everyone who borrowed it knew what a very special book it was to me. It taught me to be a salamander morphologist and introduced me to the arcane nature of morphological nomenclature. It is a wonderful book, still extremely useful, and I could not be happier with the decision to reprint it.

The production is outstanding. The color frontispiece seems better than my original, and the plates are superbly reproduced, on higher quality paper than in the original. The binding is designed to last. I especially like the very attractive paper wrappers, a vast improvement on the original.

This book will introduce the reader to all aspects of the visible morphology of *Salamandra salamandra*. The greatest strengths of the book are the excellent descriptions accompanied by lists of synonyms for sometimes confusing morphological nomenclature, and the excellent plates, which are of exceptional quality. The morphological descriptions are of lasting value even though much has been published on nearly every topic since the book appeared. Descriptions of the skeleton, musculature, peripheral nervous system, gross anatomy of the brain, the heart and vascular system, and the urogenital system are accurate and remain fully usable. Because so much recent research has expanded knowledge, information on respiration, internal anatomy of the brain, the endocrine system, the sensory systems, the skin, and some other sections are of less value, except with respect to generalizations and topography. Interspersed throughout the text are commentaries that

are often interesting and informative, and which continue to offer suggestions for additional research.

The bibliography is superb—essentially complete up through 1933. I have made extensive use of it in my own research and still refer to it with regularity. The long introduction by Professor Cole is historical and, to me, fascinating in its accounts of early work on *Salamandra* by great figures in the history of biology. Chapter I deals with taxonomy and life history. This has largely been superseded, but it is of historical interest.

A special feature of the reprint is a two-page introduction to the authors by Kraig Adler, Guest Editor of this volume. There is a delightful photo of Eric Francis, who lived until 1993 when he died at age 93, and a formal photo of Francis Cole.

A ten-page introduction to the new volume by James Hanken updates the most significant work on salamander anatomy published since 1934 and includes a very useful bibliography. I enjoyed this lively and informative feature.

I would like to think that every student of amphibian biology would want this book at hand, but I realize that not all herpetologists are interested in anatomy. The standard textbook on amphibians by Duellman and Trueb has excellent anatomical descriptions and figures. But for more in-depth coverage and for a magnificent intellectual accomplishment accompanied by figures of extraordinary value, this is a book that has no peer for amphibians. This is a book for beginning graduate students as well as more senior professionals, and I heartily recommend it.

Once again the Facsimile Reprints in Herpetology series has produced a book that will truly serve all herpetologists, and I congratulate Kraig Adler not only for conceiving the series but for establishing a high standard of quality production.

Artwork and Slides Wanted for *HR*

We are always interested in obtaining illustrations of herpetological subjects for publication in *Herpetological Review*. Generally, original drawings should be of a scale that would permit reduction to fit a 90-mm wide column. Original art, or high quality photocopies, should be packaged to ensure safe delivery and sent to the Editor. Alternatively, we would be pleased to receive material in electronic format; consult the Editor for appropriate file formats and sizes.

Also, we are interested in evaluating outstanding color slides of amphibians and reptiles for possible use on future *HR* covers. When reviewing material for submission, photographers should keep in mind the vertical format of our covers. In addition to highlighting outstanding photography, our cover subjects should lend themselves to communication of biologically interesting information through accompanying text. If you would like to have your work considered, please contact the Editor ***prior*** to sending any slides. We prefer to review images as low-resolution JPEG files before requesting examination of original slides. Postal and e-mail addresses are listed on the inside front cover.

Information for Contributors

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes of a semi-technical or non-technical nature, as well as book reviews, institutional features, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (see inside front cover for Editor's address). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ukans.edu/~ssar/HRinfo.html#cont>

Reprints

Reprints of notes or articles published in ***HR*** should be ordered using the forms provided to authors as the issue goes to press. Proofs are not sent to authors of Geographic Distribution notes; these authors should indicate (at time of submission) whether reprints are desired and if so, the appropriate order forms will be sent prior to publication. These are also available upon request from the Editor or Managing Editor.

Advertising

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Peabody Museum of Natural History, Yale University, P.O. Box 208118, New Haven, Connecticut 06520-8118, USA. Periodical postage rates are paid at New Haven, Connecticut with additional entry offices. **POSTMASTER:** Send address changes to *Herpetological Review*, Attn. Donald Schmitt, SSAR Membership Office, P.O. Box 253, Marceline, Missouri 64658, USA. Please notify Breck Bartholomew, SSAR Publications Secretary (contact information below) regarding missing or damaged issues.

SSAR Publications

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive pre-publication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: <http://www.herplit.com/SSAR/>

Catalogue of American Amphibians and Reptiles

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available by subscription only. See inside front cover to start annual subscription. Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1 – 760		US $460
INDEX TO ACCOUNTS 1 – 400: Cross-referenced, 64 pages		$6
INDEX TO ACCOUNTS 401 – 600: Cross-referenced, 32 pages		$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)		$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)		$35
INCOMPLETE SET: NUMBERS	1 – 190	$75
	191 – 410	$85
	411 – 760	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com.

How does one test the validity of a population enumeration technique? Most validation studies perform "soft" validation; they attempt either to correlate the counts from two or more methods (Fitch 1992) or to compare the economic costs, difficulty, time requirements, or non-economic costs of carrying out selected methods (Strong et al. 1993). Soft validation does not establish the accuracy of a method. "Hard" validation, in which population estimates are checked against the true values, is obviously desirable, but it is always difficult to do and might be impossible for some systems. Hard validation studies involving reptiles or amphibians are rare and usually involve the artificial stocking of a bounded plot (Henke 1998; Rose and Armentrout 1974).

Distance sampling is a relatively new technique (Buckland et al. 1993) that has gained considerable favor for certain herpetological sampling problems (Akin 1998; Thompson et al. 1998), but has yet to be subjected to hard validation tests for reptiles or amphibians. As with strip transect searches (Duellman 1987), distance sampling involves searching for animals within a certain distance from a transect centerline, but it differs from strip transects in requiring the measurement (or estimation) of the perpendicular distance from the centerline to each detected animal. Whereas strip transect searches make the implicit assumption that detection is complete for animals within the strip, distance sampling requires only that all animals *near the centerline* be detected. The distribution of sighting distances to animals off the centerline is used to model detectability in the vicinity of the centerline, but it is only the centerline density estimate that is used and extrapolated to the habitat at large.

Because the centerline density is extrapolated to the overall habitat, it is essential that the centerline conditions be representative of the habitat. Strip transects make a similar assumption about the representativeness of the entire strip, but the corresponding distance sampling assumption is more problematic in that the centerline of many transects is a road or trail, hardly representative of adjacent habitat. In addition to having different ground cover

and animal use patterns than surrounding habitat, trails in forested areas are associated with light gaps that alter the density and form of vegetation (hence visibility, basking opportunities, etc.). To be truly representative, a distance sampling centerline must be placed randomly in relation to animal position and habitat heterogeneity. These strictures dictate that trails or roads should not be followed, but this is impractical in most forested habitats.

The other key assumptions of distance methodology are that each animal is counted only once and that the perpendicular distance from the animal to the centerline is estimated without error and prior to any movement of the animal towards or away from the centerline/observer. Depending on the study species, these assumptions would not be troublesome for many reptiles and amphibians.

Distance sampling seems ideally suited for the many species of amphibians and reptiles that are rarely seen or hard to capture, because marking, recapture, or handling of animals is not required. One can sum rare detections over many sampling occasions, and there is no minimum number of detections needed for a sampling occasion to be useful. There is no uncertainty about the size of the area sampled, and one obtains an absolute population density estimate that is insensitive to habitat structure, species, or the capabilities of the searcher (Rodda 1993). The key disadvantages of distance sampling for reptiles and amphibians are that one *must* detect 100% of the animals on the unbiased centerline and that detections must be gathered over an amount of time and space sufficient to accumulate an adequate sample size. Thus one might have difficulty using distance sampling to answer a question such as, "Do rainbow snakes reach peak density in a particular wetland in May?"

We conducted a hard validation study of distance sampling for forest geckos and snakes on Guam. We compared the estimates produced by distance sampling to true local gecko densities based on subsequent total removal of all animals and vegetation from sealed 10 x 10 m plots (Rodda et al. 2001). For brown treesnakes (*Boiga irregularis*), we compared distance sample estimates to densities based on mark-recapture estimates that we had in turn validated in adjacent fenced 1-ha plots by comparing mark-recapture estimates to total removal of all snakes (Campbell 1996). The gecko comparison was done sequentially, as the total removal method alters vegetation and therefore could not be carried out concurrently with the distance sampling.

Methods.—We searched for forest geckos and snakes in a 6.5-ha patch of tangantangan (*Leucaena leucocephala*) forest north of the grenade range at Northwest Field, Andersen Air Force Base, Guam (N 13.6373–13.6399; E 144.8616–144.8643), 19 January 1993 to 29 November 1994. Within this patch were four 1-ha plots circumscribed by trails and penetrated by three parallel internal transect trails spaced 25 m apart. Sighting of forest squamates was facilitated because all searching was done at night when the many small leaflets of the dominant tree, *Leucaena leucocephala,* fold closed (mean percentage of tree basal area due to the species *L. leucocephala* = 61%, N = 7 removal plots). The forest canopy in this area is very low (mean = 5.4 m, N = 7 removal plots) and is unusually open (mean distance to daytime disappearance of a human = 15.7 m, N = 1000). Mean forest canopy cover was 69% (N = 7 removal plots). Because of this naturally incomplete canopy, creation of the transect trails did not greatly alter forest structure. Negligible movement towards or away from the observer was noted in sighted animals, which were illuminated by spotlight.

Distance estimates were obtained by two experienced observers who periodically checked sighting distance estimates against measured distances (a telescoping rod marked at 0.1 m intervals was extended perpendicularly from transect centerline to the sighting point). They walked each transect five times quarterly, for a total of 36.2 km of transect searched on both sides of the trail/centerline. Results from other transects (in manipulated or snake-controlled plots: Campbell 1996) were not included in the distance validation data presented here. Sightings > 4 m from the transect centerline were extremely sparse and were not used in the analysis. Because of uncertainty about the species identity of small geckos, all gecko species were pooled. Based on known identities (96% of sighted geckos were identified to species), the majority (88%) of these sightings were *Hemidactylus frenatus*, the remainder *Lepidodactylus lugubris*. It is possible that some individuals of *Gehyra mutilata* were present; none was definitely sighted, though one was found in a removal plot. The only other sighted squamate was the brown treesnake, *Boiga irregularis*. Snakes were analyzed separately from geckos.

Conventional distance analytical methods (Buckland et al. 1993) were used, with cut points for distance categories set at 0, 1, 2, 3, and 4 m (i.e., sightings grouped in the ranges 0–1.0 m, 1.01–2.00 m, etc.). Alternate cut points were investigated but did not appreciably affect density estimates. Model selection was guided by program DISTANCE; alternate models provided nearly identical density estimates. Estimated sighting distances were pooled over time for the four 1-ha study plots, providing sample sizes of effort (36.2 km), samples (4 plots), and observations (1853 geckos and 51 snakes).

Absolute population density measurements, by total removal, were obtained using the methods described by Rodda et al. (2001). Briefly, canopy separation and ground-level aluminum flashing were used to prevent the movement of lizards into or out of the sample plots while the vegetation was removed and all vertebrates identified, measured, and weighed. Plots were selected on the basis of representative canopy coverage and plant species composition. Four 5 x 5 m plots and one 10 x 10 m plot within the area surveyed using distance methods were censused 16 Feb–14 May 1995. Four 10 x 10 m additional samples from the same area were censused 28 Jan–11 Feb. 1999. Because the two series produced nearly identical mean gecko densities (3350/ha v. 3450/ha), these were pooled for comparison to distance estimates.

Mark-recapture was used only for snakes, following the methods described in Campbell (1996) and using program MARK (White and Burnham 1999). Through saturation removal of snakes from fenced plots, Campbell demonstrated that the true snake density was well within the 95% confidence limits of mark-recapture estimates made with this method on these plots at the time this work was carried out. Briefly, we captured brown treesnakes using snake traps (Rodda et al. 1999) and hand capture over six 15–22 day periods simultaneous with the distance sampling. All captives were double marked using PIT tags and paint markings. Exploration of the resulting capture history matrices with various open population models consistently indicated a best model (selected on the basis of Akaike's Information Criterion) that varied capture probability, p, in accordance with snake snout-vent length

(small snakes were less frequently captured), but with capture probability and apparent survivorship, ϕ, constant over time. "Apparent survivorship" quantifies the probability of a snake dying or moving permanently out of a study plot between daily trapping occasions. Emigration so measured was high enough (2.5–17.5%/day) to preclude analysis with closed mark-recapture models. Snake abundance in each plot was estimated as size-stratified n-bar/p-hat, where n-bar is the mean number of captures/day and p-hat is the maximum likelihood estimator of mean capture probability. Density was estimated by dividing estimated abundance by each plot's nominal trap grid area (1 ha). Twenty-four venues (four plots by six time periods) provided density estimates, but ten of these involved plots for which the snake density had been manipulated. The fourteen density estimates from unmanipulated plots were averaged for comparison to the one distance estimate obtained concurrently.

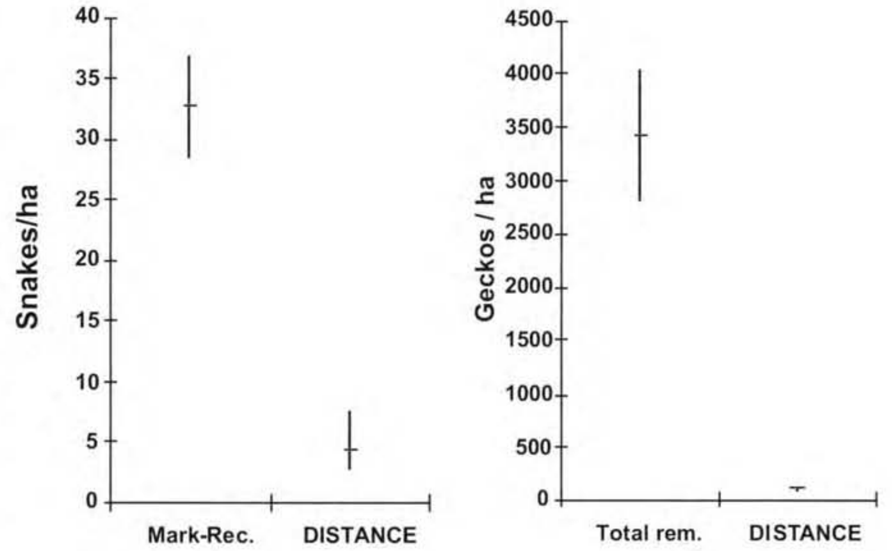

FIG. 1. Distance sampling estimates for brown treesnakes, *Boiga irregularis*, and geckos (*Hemidactylus frenatus*, *Lepidodactylus lugubris*, and *Gehyra mutilata*) on Guam in relation to mark-recapture (snakes) or total removal estimation (geckos). Distance estimates show maximum likelihood estimate with 95% confidence intervals. The other values are mean +/- SE.

Results.—The detection distances analyzed by DISTANCE showed the expected smooth decline with increasing distance from the transect centerline (geckos: 721, 602, 390, and 140; snakes: 29, 21, 7, and 9) and had excellent model goodnesses of fit (geckos: $\chi^2 = 0.71$, df = 1, P = 0.4; snakes: $\chi^2 = 1.39$, df = 1, P = 0.24). For both data sets, the selected model used the uniform key and cosine adjustment. However, the density estimate obtained for geckos was 100.1 geckos/ha (95% CL: 85.6–117.1), whereas the mean density estimate obtained by direct count (total removal) averaged 3416.7 geckos/ha (SE = 608). Thus the distance estimate for geckos was low by a factor of about 34 (Fig. 1). The distance density estimate for snakes was 4.4/ha (95% CL: 2.6–7.4), whereas the validated mark-recapture population estimates (N = 14) averaged 32.7/ha (SE = 4.0). Thus the distance estimate for snake density was low by about a factor of 7 (Fig. 1).

The gecko species composition estimated from sighted individuals was overwhelmingly *Hemidactylus frenatus* (88%), whereas subsequent total removal censuses indicated that less than half of the gecko individuals present (46%) were of that species. The majority (52%) were *Lepidodactylus lugubris*.

Discussion.—Does the discrepancy in gecko species composition between visual sightings (88% *Hemidactylus*) and census results (46%) reflect detection differences among gecko species or were geckos misidentified or often not-identified to species during visual searches? The percentage of unidentified geckos (4.1%) was small relative to the total sample, indicating that the large discrepancy could not be made up by more complete identification of geckoes sighted. The two observers gave virtually identical percentages of *Hemidactylus* in their visual samples (87.3 v. 87.7%), suggesting that few identifications were in error. It is likely, however, that detection differed between these species. *Lepidodactylus* is found mainly in foliage, where visibility is reduced, whereas *Hemidactylus* is most often found in more visible sites on branches, limbs, and trunks. Thus we expected that detection would be more complete for *Hemidactylus*. If one assumes that all visual identifications were correct and that the proportional representation of unidentified species was the same as for the identified geckos, the distance estimate for *Hemidactylus* would be 88/ha (CL 75–103/ha), which underestimated the true value of 1572/ha low by a factor of about 18. If one combines the small uncertainty associated with species identification with the distance sample confidence limits, the *Hemidactylus* uncertainty ranges 72–104/ha, implying an error factor of 15–22 fold. The corresponding values for *Lepidodactylus* are 12/ha (CL 10–14/ha), which underestimated the true density of 1777/ha by a factor of about 148. Adding in the identification uncertainty broadens the total uncertainty range for this species' estimate to 10–18/ha, implying an error factor of 98–181.

The population density estimates provided by DISTANCE in this case were severely biased in comparison to higher validity methods. As evidenced by the different gecko species composition of the contrasted methods, the bias was different for different species even within the same guild and body size range. Before concluding that distance sampling is inappropriate for this system, however, it is desirable to question possible sources of error in the higher validity methods. Each method makes assumptions, but the following seem to us to have the greatest likelihood of error.

Open mark-recapture analysis assumes negligible individual heterogeneity in capture probability. If this assumption is invalid for brown treesnakes, the true population densities would be higher than reported here, and the estimated bias of the distance estimates would be greater.

Open mark-recapture analysis also assumes the absence of either trap happiness or trap shyness. The existence of trap happiness would exacerbate the apparent bias of distance sampling for snakes, whereas trap shyness would have the opposite effect. Note that the mouse attractant used in the snake traps could not be eaten by captured snakes, so trap happiness would not be expected. In

closed model analysis of brown treesnake trap captures we have detected only limited evidence of either type of behavioral response (Rodda and Dean-Bradley, unpubl. data), suggesting that the observed difference between mark-recapture and distance sampling is not attributable to trap shyness.

The small sample plots used for total removal population density estimation might have been non-representative. The selection criteria seem unbiased, and extensive glueboard surveys and visual searches failed to document any evidence of non-representation. We expect that only random bias would be produced by failure of this assumption.

Which distance assumptions might be invalid? The use of trails rather than randomized unimproved transects for distance sampling centerlines violates a key method assumption, that transects be placed randomly in relation to habitat. In this specific case, the transect "centerline" is a 2-m wide band spanning the trail. If squamate sighting rates were lower on trails than when walking cross-country through the forest, our use of trails could produce the observed bias. It is our experience, however, that sighting rates are not higher when walking cross country through the forest on Guam, but drop to near zero, because of visual interference by vegetation. Furthermore, if trails have any effect on the distribution of these species we would expect that heliophilic squamates would seek out the sides of trails, as the light gaps created by trails produce more vegetation of a suitable height and these provide more basking and foraging opportunities. Thus, our expectation was that use of trails for transect centerlines would bias distance estimates upwards, not downwards as observed.

Violation of the assumption that all squamates present on the centerline were detected most likely produced the observed bias. It seems likely to us that vegetation concealed many active squamates, and that inactivity of others would account for their unavailability for detection. Intensive visual searches of brown treesnakes in finely-gridded areas on Guam produce an average detection probability of < 9% (usually < 5%; Rodda et al., unpubl. data). If one can see only 9% (or less) of the snakes that are present in a forest, it is unrealistic to expect distance sampling to produce unbiased estimates of forest squamate population density. Because of the ubiquitousness of visual barriers in a forest, we suggest that distance sampling is unlikely to be valid for absolute densities of forest vertebrates detected exclusively by sight.

Does the discrepancy in gecko species composition between visual sightings (86% *Hemidactylus*) and census results (46% *Hemidactylus*) reflect detection differences among gecko species, or were visually-sighted geckos unidentified or misidentified frequently enough to account for the discrepancy? The percentage of unidentified geckos (4.1%) was small relative to the number identified; this could not account for the discrepancy. Misidentification cannot be unequivocally ruled out, but we believe that the primary cause of the discrepancy is the different microhabitats used by these geckos: *Lepidodactylus lugubris* is found mainly in foliage, where visibility is reduced relative to the branch/trunk sites preferred by *Hemidactylus frenatus*.

Also, if detection on the centerline is not 100% and differs among species, distance estimates cannot be used as an index of abundance when comparing species. For example, the distance estimator for *Hemidactylus frenatus* cannot be compared to that for *Lepidodactylus lugubris,* even if used only as an index of abundance. However, it might be possible to make temporal comparisons within a single species. Validation studies among different seasons, species, and habitats would be needed to determine if the ratio of undercounting is consistent enough for distance sampling to have utility as a single species index.

Acknowledgments.—Craig Clark was a cornerstone of support for all of the field work involved in this project. We were also ably assisted by Jay Graham, Matt Reid, Tom Fritts, Thomas Sharp, Grant Beauprez, Todd Mabee, Stan Kot, and numerous appreciated volunteers. The Department of Defense Legacy Program and the U.S. Department of the Interior's Office of Insular Affairs provided financial support. Andersen Air Force Base (H. Hirsch) provided access to field sites. Ken Burnham, Gary White, and David Anderson provided superlative training on the software used for the analyses. Kathy Dean-Bradley, Tony Tucker, Teri Kman, and Jimi Gragg suggested improvements to the manuscript.

A Comparison of the Efficacy of Survey Methods for Amphibians Breeding in Small Forest Ponds

Although researchers have studied amphibians for many years, status assessments have been hampered by a lack of standards and protocols for inventory and monitoring. Heyer et al. (1994) and Olson et al. (1997) provide a foundation in their reviews of methods used for measuring and monitoring amphibian biodiversity. It is clear from these reviews that no single method effectively assesses all species and that more information is needed on the efficacy of approaches for surveying and monitoring amphibians in differing geographic regions and habitat types.

Forests and associated wetlands are dominant components of glaciated landscapes of the Upper Great Lakes Region, including the states of Michigan, Minnesota, and Wisconsin, USA (Dahl and Zoltai 1997; Frayer 1997). Because timber harvest rates have increased in recent decades (Vasievich et al. 1997), disturbance from land management activities also has increased. These disturbances affect both wetlands directly and characteristics of the surrounding forest on which wetland communities depend (deMaynadier and Hunter 1995; Pauley et al. 2000; Semlitsch 2000). Wetlands are embedded in, and strongly linked ecologically to the surrounding forest (Palik et al. 2001). This is also true of amphibians in such habitats. They breed in small seasonal forest wetlands and live in the adjacent forest uplands during the remainder of the year (deMaynadier and Hunter 1999; Gibbs 1993; Hecnar and M'Closkey 1996, 1997; Wilbur 1980). In small seasonal forest ponds, water levels can fluctuate widely and the amphibian breeding season is short. There is a need to examine the efficacy of survey methods for assessing amphibians in such habitats.

In this paper, we assess amphibian survey methods in small seasonal forest ponds. Our objectives were to: 1) determine the efficacy of three amphibian survey methods (breeding call, dip net, and funnel trap surveys) for detecting four species (*Rana sylvatica*, *Pseudacris crucifer*, *P. triseriata*, and *Ambystoma laterale*); 2) compare the efficacy of these methods used singly and in combination for documenting species occurrence; and 3) determine the efficacy of two additional methods (egg and metamorph surveys) for *R. sylvatica*.

Materials and Methods.—We conducted the study from 1998 to 1999 at 76 seasonal forest ponds in north central Minnesota in the Sucker Lakes watershed, Cass County, and in the Rice River watershed, Itasca County. In these forested watersheds, ponds are abundant and their morphology, hydroperiods, and animal and plant communities are highly variable. Candidate ponds were identified on 1:15,840 scale color infrared photographs (Brooks et al. 1998). To maximize the likelihood of identifying ponds with seasonal hydroperiods (i.e., ponds in which water is seasonally present), wetlands that also occurred on the National Wetlands Inventory (Wilen 1990) were excluded from consideration. From the remainder, we randomly choose up to five ponds in each of 13 ecological Landtype Association - Landtype (Albert 1995) combinations found on the watersheds, mostly within undisturbed, mature forest stands. The 76 selected ponds ranged in size from 0.04 to 0.20 ha, 74 had seasonal hydroperiods in 1998, and they occurred within a variety of forest types.

We examined the efficacy of survey methods for four species of amphibians: wood frogs (*Rana sylvatica*); spring peepers (*Pseudacris crucifer*); western chorus frogs (*P. triseriata*); and blue-spotted salamanders (*Ambystoma laterale*). We used three primary methods to survey these species during 1998 and 1999: breeding call (C), dip net (D), and funnel trap (T) surveys.

A modified Wisconsin protocol (Kline 1998; Mossman and Hines 1985; Mossman et al. 1998) was used for the C survey, and was conducted once during each of two sampling periods in both years: 12–15 April to assess wood frogs and western chorus frogs; and 17–19 May to assess other calling amphibians. Each pond was visited between 1915 and 0135 h, and after about a minute of acclimation, one person recorded the presence of all species of amphibians calling during a 3-min period.

The D survey was conducted once each year from 24–28 May and 3 June in ponds containing water to sample amphibian larvae. Larvae were readily identifiable by this point in the season. Ponds were swept with aquatic D-shaped dip nets (30 cm width, 20 cm long canvas bag, 1 mm mesh bottom, with 10 cm long canvas skirt) for a total of 15 person-min, regardless of pond size, between 0800 and 1640 h. An effort was made to first sample all habitat elements in a pond, then habitat elements most likely to produce captures. Captured amphibians were held in buckets until the sampling period ended, then were identified, counted, and released. Although we captured both larvae and occasional adults, only larvae were included in the analysis.

T surveys also were conducted to sample amphibian larvae. We used unbaited metal traps of two different mesh sizes in 1998: four (6 x 6 mm) openings per 2.5 cm and eight (3 x 3 mm) openings per 2.5 cm [Cuba Specialty Manufacturing Co., Fillmore, New York; G-40 and G-48M]. Traps were spaced evenly around each pond in shallow water perpendicular to shore. They were placed in water deep enough to submerge the trap entrance, yet provide air for amphibians to breathe. We set two to six traps (one to three of each mesh size) around each pond, alternating mesh sizes from a random start. The number of traps was chosen to approximate an equivalent effort per unit of pond surface area, which averaged about 210 m^2/trap. T surveys were conducted once in each pond, for three consecutive days, from 3–25 June in 1998 between 0800 and 1600 h. Captured amphibians were identified to species, counted, and released. Although we captured both larvae and occasional adults in traps, only larvae were included in the analysis. In 1998, we determined that mesh size of traps was of no consequence to wood frog larvae capture rates, but the smaller 3 x 3 mm mesh size produced higher capture rates for the smaller-sized larvae of spring peepers and blue-spotted salamanders (Buech and Egeland 2002). Thus, in 1999, we again trapped each pond for three days between 8 June and 9 July using only 3 x 3 mm mesh traps. Summer precipitation was exceptionally low in 1998 and exceptionally high in 1999; consequently, we were able to trap in

more ponds in 1999. Additionally, because ponds contained more water in 1999 and we wanted to maintain a relatively constant effort per unit of surface area, we used more traps in 40% of ponds in 1999.

Wood frog egg masses are highly visible and often clumped in one location, which suggested that egg mass surveys might be effective for determining occupancy (Crouch and Paton 2000). Surveys for wood frog egg masses (E) (1998 and 1999) and wood frog metamorphs (1999) were conducted to determine if single-visit surveys for these life stages provide useful information. Each pond was visited within a week after the April breeding call survey to look for egg masses. We searched ponds thoroughly between 0800 and 1600 h without time limit, until we either found and recorded the number of egg masses, or were fairly confident that eggs were not present. Similarly, we visited ponds in mid-summer (12–23 July) to conduct a survey for recently metamorphosed wood frogs, and recorded the number observed during a 10 person-min search around the perimeter of each pond.

We summarized data by reducing it to presence-absence information and counted how many ponds a particular method or combination of methods recorded each species as being present for 1998 and 1999. The measure of efficacy was taken as the pond count for a method or combination of methods, expressed as a proportion of the number of ponds in which a species was recorded by all methods combined. For example, if we surveyed 50 ponds and heard wood frogs calling in 30, and we learned by looking at all survey methods that wood frogs were actually present in 40 of the 50 ponds, the efficacy of the calling survey for wood frogs in that year would be stated as 0.75. We combined years by summing the pond counts over 1998 and 1999. In addition to the four amphibian species already mentioned, one other taxon (gray treefrog, *Hyla versicolor*) was included in analyses of species richness. Log-linear and contingency table analyses were used in SYSTAT 8.0 (SPSS, Inc. 1998) to compare the efficacy of methods and where appropriate, Pearson's Chi-square statistic (χ^2) is reported.

Results.—We compared the efficacy of C, D, and T surveys for assessing reproductive activity of the three anurans most frequently found at our ponds (Fig. 1). For wood frogs, these methods yielded similar results in 1998 (Fig. 1a), but efficacies were not homogeneous in 1999 ($\chi^2 = 37.15$, df = 2, $P < 0.001$); C surveys recorded wood frogs in fewer ponds than recorded by either D or T surveys. For wood frogs, the combined-year efficacy of D and T surveys was better than for C surveys ($\chi^2 = 10.33$, df = 1, P < 0.001 and $\chi^2 = 9.39$, df = 1, P < 0.002, respectively).

Efficacy patterns of C, D, and T surveys for spring peepers (Fig. 1b) and western chorus frogs (Fig. 1c) were similar in both years. In 1998, 1999, and both years combined, efficacies of C, D, and T surveys were not homogeneous for both spring peepers ($\chi^2 = 70.94$, df = 2, $P < 0.0001$; $\chi^2 = 76.84$, df = 2, $P < 0.0001$; $\chi^2 = 134.85$, df = 2, $P < 0.0001$; respectively) and western chorus frogs ($\chi^2 = 35.40$, df = 2, $P < 0.0001$; $\chi^2 = 12.35$, df = 2, $P < 0.002$; $\chi^2 = 43.06$, df = 2, $P < 0.0001$; respectively). In both years combined, C surveys detected these frogs more frequently than either D (spring peepers $\chi^2 = 134.75$, df = 1, $P < 0.001$; western chorus frogs $\chi^2 = 31.16$, df = 1, $P < 0.001$) or T surveys (spring peepers $\chi^2 = 44.66$, df = 1, $P < 0.001$; western chorus frogs $\chi^2 = 31.16$, df = 1, $P < 0.001$). D and T surveys generally yielded similar results except the T survey recorded spring peepers in many more ponds than did the D survey (combined-years analysis: $\chi^2 = 37.36$, df = 1, $P < 0.001$), especially in 1999.

Combinations of survey methods, especially combinations that included a C survey, did a better job of detecting all three species (Fig. 1). Call plus dip net surveys (CD) and call plus funnel trap surveys (CT) yielded similar results. These combinations were better than dip net plus funnel trap (DT) surveys for spring peepers and western chorus frogs (χ^2 range in 4 comparisons: 30.00 to 62.45, df = 1, $P < 0.001$). For wood frogs, only CD surveys differed from DT surveys ($\chi^2 = 5.48$, df = 1, $P < 0.019$). C surveys detected spring peeper and western chorus frog reproductive activity almost as well as CD and CT surveys, however, C surveys detected spring peepers in fewer ponds than CT surveys ($\chi^2 = 7.27$, df = 1, $P < 0.007$). For wood frogs, the addition of either D or T

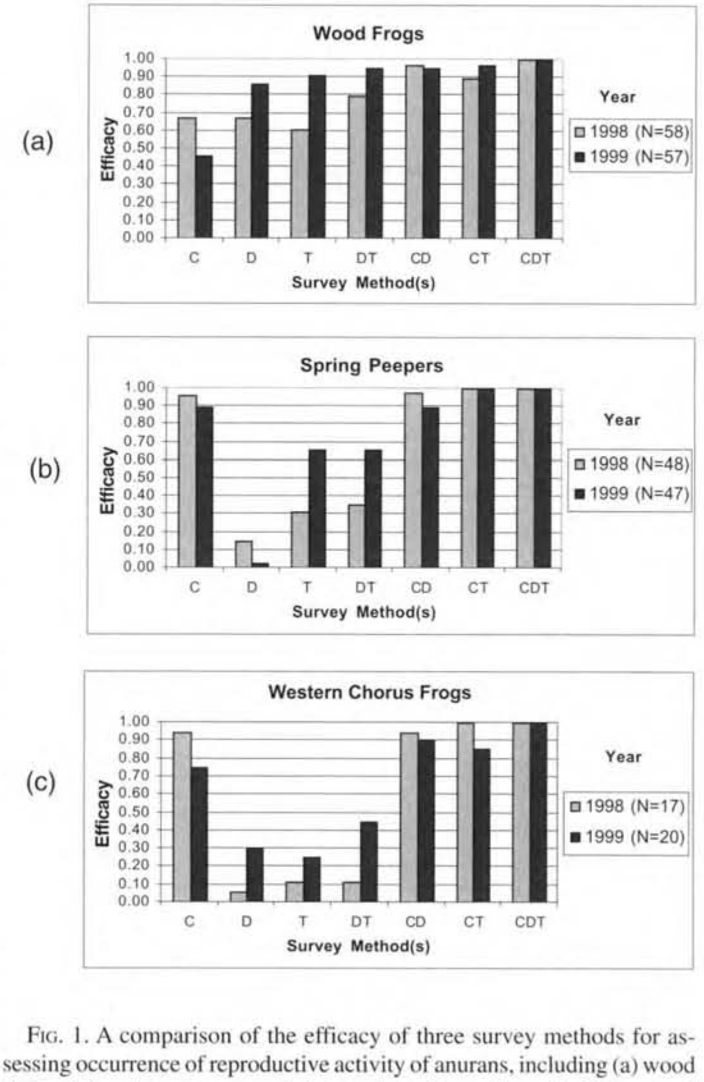

FIG. 1. A comparison of the efficacy of three survey methods for assessing occurrence of reproductive activity of anurans, including (a) wood frogs, (b) spring peepers, and (c) western chorus frogs, in 76 seasonal forest ponds in north central Minnesota in 1998 and 1999. Methods used were breeding call (C), dip net (D), and funnel trap (T) surveys, which were analyzed singly and in combination. The measure of efficacy was taken as the pond count for a method or combination of methods expressed as a proportion of the number of ponds in which a species was recorded by all methods combined. The sample size listed for each year is the total number of ponds in which reproductive activity was recorded for the species by any of the three methods.

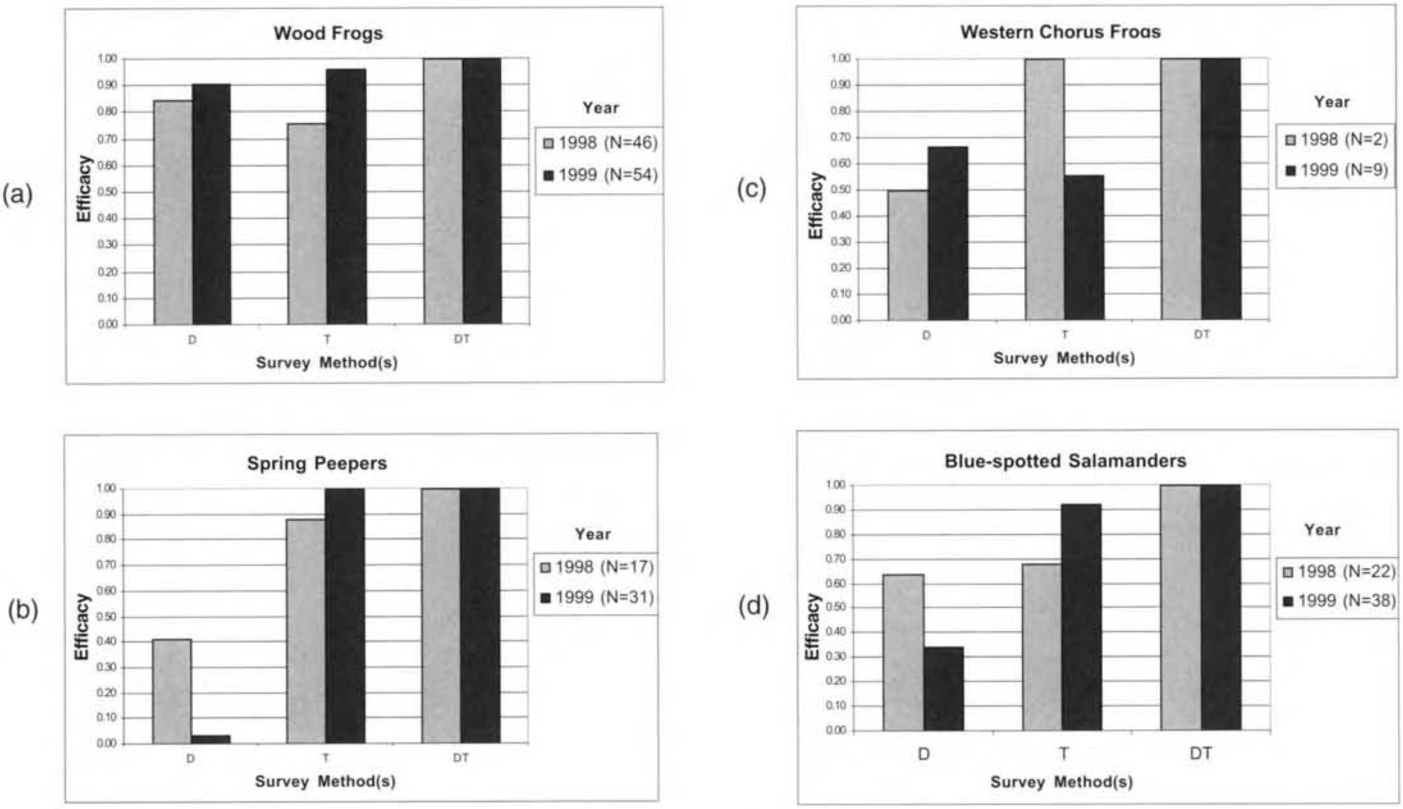

FIG. 2. A comparison of the efficacy of two survey methods for measuring the presence of (a) wood frog, (b) spring peeper, (c) western chorus frog, and (d) blue-spotted salamander larvae in 76 seasonal forest ponds in north central Minnesota in 1998 and 1999. Methods used were dip net (D) and funnel trap (T) surveys, which were analyzed singly and in combination. The measure of efficacy was taken as the pond count for a method or combination of methods expressed as a proportion of the number of ponds in which a species was recorded by all methods combined. The sample size listed for each year is the total number of ponds in which a species larva was recorded by either of the two methods.

surveys to C surveys detected their presence more effectively ($\chi^2 = 48.39$ and 40.67, df = 1, $P < 0.001$).

In a second analysis, we disregarded C surveys and reanalyzed data from D and T surveys for wood frog, spring peeper, western chorus frog, and blue-spotted salamander larvae (Fig. 2). These methods might be chosen to assess non-calling amphibians. T surveys did a better job than D surveys in documenting the occurrence of larvae for two of the four species (Fig. 2b and 2d) ($\chi^2 = 61.12$ and 19.17, df = 1, $P < 0.001$, respectively, for spring peepers and blue-spotted salamanders); however, the western chorus frog (Fig. 2c) sample size was low.

Multiple visits contributed to the efficacy of T surveys (Fig. 3). In both years combined, 94% of 86 ponds known to contain wood frogs were identified after only one day of trapping, and 99% after two days of trapping. However, we also captured a total of 9395 wood frog larvae in these ponds during both years. For less abundant species [blue-spotted salamanders (N = 48 ponds; 272 larvae) and spring peepers (N = 46 ponds; 377 larvae)], about 70% of ponds known to contain the species were identified after the first day and 90% after the second day. Results were similar for the chorus frog, which was found in only 6 ponds (10 larvae) that we trapped. The known complement of species in ponds also was identified in about 70% of ponds after one day and in 90% of ponds after two days of trapping.

Survey data for wood frogs were reanalyzed to include E surveys to document reproductive activity (C, E, D, and T surveys in Fig. 4a) and presence of only their eggs or larvae (E, D, and T surveys in Fig. 4b). Efficacy of E surveys tended to be more variable among years compared to other survey methods. Furthermore, with the exception of the 1999 C survey, E surveys documented the presence of wood frogs in fewer ponds than any of the other survey methods. In fact, E surveys identified only 40 and 70% of ponds known to contain either wood frog eggs or larvae, respectively, in 1998 and 1999. As in Fig. 1, the best two-method survey

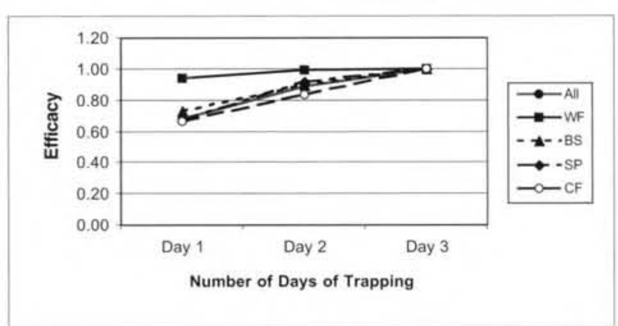

FIG. 3. Efficacy of T surveys for identifying ponds known to contain wood frogs ([WF]; N = 86 ponds), blue-spotted salamanders ([BS]; N = 48 ponds), spring peepers ([SP]; N = 46 ponds), chorus frogs ([CF]; N = 6 ponds), and the known-species complement ([All]; N = 91 ponds), in relation to the number of days trapped. The measure of efficacy is the cumulative proportion of ponds known to contain the species or the known complement of species after 1, 2, and 3 days of trapping.

sets for documenting reproductive activity of wood frogs were CD or CT surveys (Fig. 4a). Of these, only the CT survey combination was worse than the three-method, CDT combination ($\chi^2 = 3.84$, df = 1, $P < 0.05$). The efficacy of both D and T surveys was improved when combined as DT ($\chi^2 = 6.77$ and 7.66, df = 1, $P < 0.01$) (Fig. 4b). In contrast, efficacies of the two-method ED, ET, or DT survey sets for documenting wood frog eggs or larvae were similar.

During the post-metamorphosis survey, recently metamorphosed wood frogs were observed in 57 ponds (data not shown), including nine ponds in which there were no eggs or larvae documented by other methods.

The number of amphibian species recorded in ponds varied both among years and among methods (Fig. 5). In 1998, the C, D, and T surveys recorded a maximum richness of four species (Fig. 5a). Although the efficacy of these methods differed, the relative distribution of species richness among ponds did not differ ($\chi^2 = 15.35$, df = 10, $P < 0.12$). In 1999 (Fig. 5b), C and D surveys identified a maximum species richness of only three species in ponds, whereas T surveys identified four species. Although the overall efficacy of the C, D, and T surveys was similar, the relative distribution of species richness among ponds was different ($\chi^2 = 39.10$, df = 8, $P < 0.001$); D surveys documented fewer species in ponds relative to other methods. Results for the three methods in combination, were similar among years (Fig. 5). However, CD and CT surveys did a better job of documenting species richness in ponds than did DT surveys in 1998 ($\chi^2 = 11.96$ and 14.18, df = 5, $P < 0.035$). The CD and CT survey combinations identified one more species (gray treefrog) in ponds compared to the DT survey combination (in both years, only the C survey detected gray treefrogs).

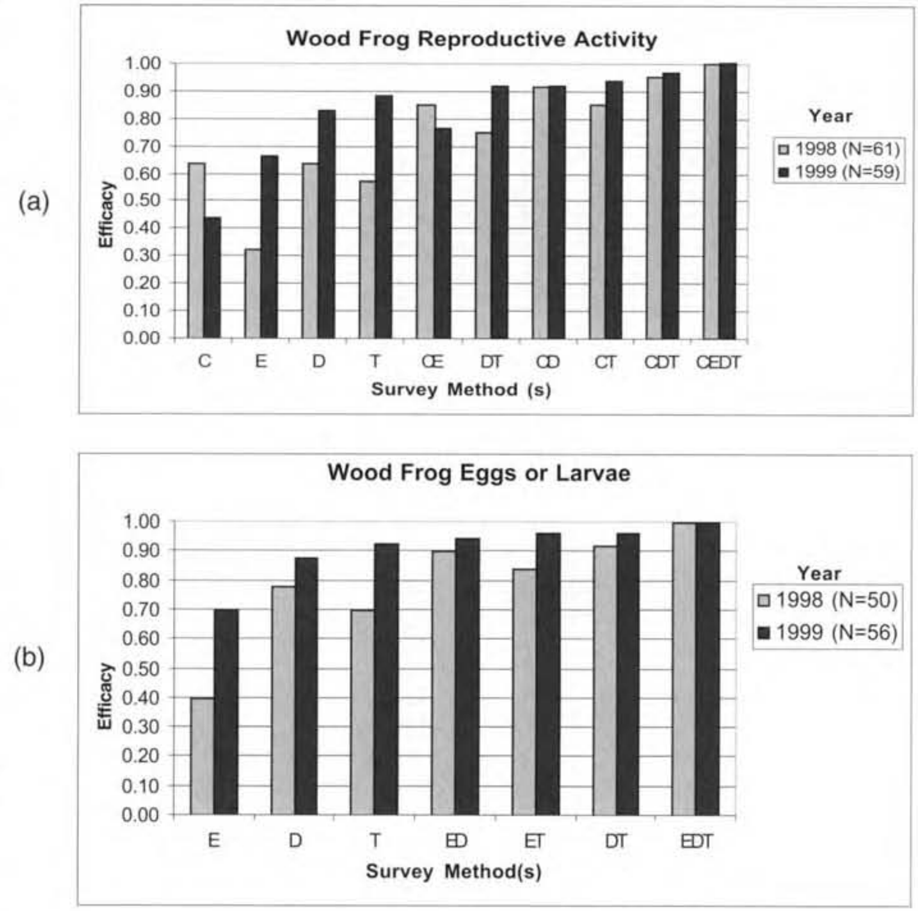

FIG. 4. A comparison of the efficacy of an expanded set of survey methods for measuring (a) reproductive activity of wood frogs and (b) presence of wood frog eggs or larvae in 76 seasonal forest ponds in north central Minnesota in 1998 and 1999. Wood frog reproductive activity was declared as occurring in a pond if it was recorded present during breeding call (C), egg mass (E), dip net (D), or funnel trap (T) surveys in that year. Wood frog eggs or larvae were declared present in a pond if they were recorded during E, D, or T surveys in that year. The measure of efficacy was taken as the pond count for a method or combination of methods expressed as a proportion of the number of ponds in which wood frogs were recorded by all methods combined. The sample size listed for 1998 and 1999 is the total number of ponds in which a) reproductive activity was recorded by any of the four methods, and b) eggs or larvae were recorded by any of the three methods.

Discussion.—Efficacy of the three primary methods was variable among species and years. Life history, reproductive phase, logistical factors, and environmental variation might account for much of this variation. For example, C surveys identified *Pseudacris* species in a much higher proportion of ponds than did D or T surveys. These species call often and over a relatively long period so they are likely to be noted when present. In contrast, C surveys identified wood frogs in ponds about as well as D or T surveys in one year but not the other. Wood frogs breed early in the season, but for only a short period, and breeding can be postponed by cold weather (Mossman et al. 1998). Consequently, it is difficult to time surveys to encompass consistently their breeding season, especially if there are large-program logistical constraints, such as the need to survey many wetlands over several days under variable weather conditions.

Several authors have suggested use of a combination of methods to meet objectives of documenting presence and relative abundance of species in amphibian communities (Heyer et al. 1994; Olson and Leonard 1997). Our results support this suggestion. A combination of a C survey with either D or T surveys documented the occurrence of calling species in more ponds than any one method alone. This is probably because of the similarity in results between D and T surveys, and the contrast between these methods and the C survey. Despite similarities between D and T surveys, there were instances in which results improved substantially by conducting both of these surveys. However, although results often improved by using multiple types of surveys, it is unknown how much of the improvement was because of adding another survey method per se, or simply because of an additional visit to the site or spending more time conducting surveys at the site.

Multiple visits to a pond clearly contributed to the efficacy of funnel trap surveys. Although a single day of trapping identified nearly all ponds known to contain wood frog larvae, this species

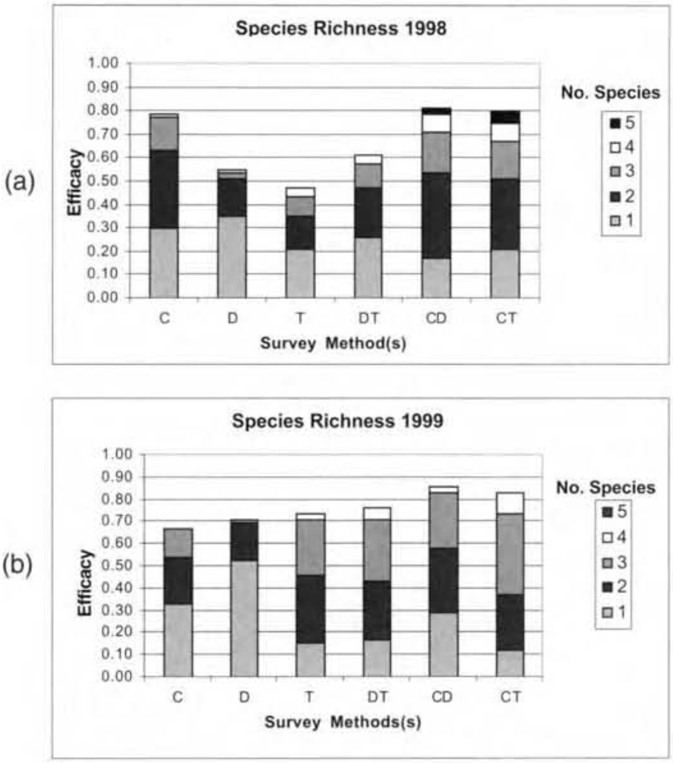

FIG. 5. A comparison of the efficacy of three survey methods for documenting the richness of amphibian species (wood frogs, spring peepers, western chorus frogs, gray treefrogs, and blue-spotted salamanders) breeding in (a) 1998 and (b) 1999 in a collection of 76 seasonal forest ponds in north central Minnesota. Methods used were breeding call (C), dip net (D), and funnel trap (T) surveys, which were analyzed singly and in combination. The measure of efficacy was taken as the pond count for a method or combination of methods expressed as a proportion of the number of ponds in which a species was recorded by all methods combined.

was very abundant. In contrast, two additional days of trapping continued to yield improvements in detection of less abundant amphibian species whose abundance was, on average, three to four percent of wood frogs. For chorus frogs, additional days of trapping might have increased the number of ponds in which they were detected. Overall, it seems that three days of trapping, as recommended by Adams et al. (1997), did a reasonable job of identifying the species composition of amphibians in small seasonal forest ponds.

A comparison of our egg survey results to those of Crouch and Paton (2000) also demonstrates the value of multiple visits. We obtained poor results from a single visit to survey wood frog eggs in 76 ponds. In 1998 and 1999, respectively, our E surveys identified only 40 and 70% of ponds known to contain wood frog eggs or larvae. In contrast, Crouch and Paton (2000) visited 15 ponds at 3 to 6 day intervals from early March to mid-April. They observed that $\geq 85\%$ of wood frog egg deposition was completed in < 8 days, but it took an average of 17.4 ($\pm$ 4.8) days for all egg masses to be deposited. Thus, they recommended that egg surveys be conducted over a three-week period and concluded that egg surveys can provide accurate information for monitoring abundance of wood frogs. Taken together, our results and those of Crouch and Paton (2000) suggest that while egg surveys can provide accurate information on wood frog reproduction, under our protocols, a single visit was not adequate to document presence. Two likely reasons for the false negatives that we recorded are failing to see communal egg masses that were present and surveying ponds before egg masses were laid. We believe the latter explanation is especially appropriate to our 1998 results; our timing was too early for a single-visit survey.

Methods differed in regard to effort required to conduct surveys under the protocols we used. E and D surveys were easiest to conduct because they only required a single visit each year and the survey itself required about 10–20 and 30–60 min at each pond, respectively. C surveys required relatively more effort. Although it took less time to conduct the survey at the site, two visits (each about 5–10 min) were required each year during nocturnal hours to assess the amphibian species that use seasonal forest ponds. T surveys required the most effort, primarily because our protocols stipulated that each wetland be surveyed once each year, and the survey itself took about 15 to 60 min for each of 4 days. Cost of equipment was zero for the C and E surveys, about US \$70 for a dip net, and about US \$8 and \$20 for one funnel trap (depending on mesh size).

As others have reported (Heyer et al. 1994; Mossman et al. 1998), methods also differed in their sensitivity to weather conditions. For one, it can be difficult to schedule surveys to cover a large number of study sites to accommodate seasonal and daily weather effects on amphibian activity. For example, we experienced difficulty in timing C and E surveys of a large number of ponds to consistently survey an explosive breeder like wood frogs. In contrast, scheduling D and T surveys is less sensitive to short-term effects of weather.

Surveying amphibians in seasonal forest ponds adds another dimension. We encountered instances of water levels that were too low to conduct surveys, concentrations of larvae in small residual puddles, ponds that prematurely dried up, and ponds that dried up and subsequently rehydrated. Such vagaries in the hydroperiods of seasonal ponds can induce daily and annual variation in data. In most cases, the consequence was inability to conduct a survey because of inadequate water. Although we tried to maintain a constant effort based on pond surface area, we suspect that high water might have diluted, and low water might have concentrated captures of amphibian larvae.

Finally, it is important to choose parameters and methods of measuring them that are congruent with objectives (Heyer et al. 1994). Although we observed differences in efficacy among methods, the fact that C, E, D, and T surveys document occurrence of species at different stages in ontogeny might affect choice of survey method. This was especially true of metamorph surveys. Metamorph surveys detected wood frogs at ponds in which no eggs or larvae were found, suggesting those surveys might have detected dispersers from other ponds. Thus, we do not recommend metamorph surveys as a tool for inventorying specific ponds.

Overall, our results suggest that while single surveys might provide representative presence-absence data for some species, we encountered biases across species and years. Use of multiple survey types improved the detection of species reproductive activity in ponds and produced less variation among years. Thus, depending on survey objectives and resources, our results support the use of multiple types of surveys (e.g., toolbox approach of Olson et al. 1997). Our results also suggest that efficacy of a survey might

improve by extending its duration or repeating it more frequently. The protocols that we used seemed appropriate for small seasonal forest wetlands in our region. If we had more resources available or fewer ponds to monitor, we would have chosen to conduct breeding call surveys for a longer period than 3 minutes, and visit ponds more frequently than once to conduct wood frog egg surveys. For seasonal forest wetlands of the upper Great lakes region, we generally recommend a combination of breeding call followed by either dip net or funnel trap (3 x 3 mm mesh) surveys conducted prior to metamorphosis.

A New Method of Sampling Arterial Blood from Large Sea Turtles

A. Y. A. ALKINDI

Some of the largest nesting sea turtle populations in the world are located in the Arabian Sea in the vicinity of the Sultanate of Oman. Green turtle (*Chelonia mydas*) nesting grounds occur along the shoreline of the Ras Al-Hadd Turtle Reserve, while olive ridley (*Lepidochelys olivacea*), loggerhead (*Caretta caretta*), and hawksbill (*Eretmochelys imbricata*) nest on Masirah Island. In the past two years, we have been involved in research projects requiring sampling of arterial blood for physiological parameters. To collect arterial blood samples, we have developed a procedure for rapid location of an arterial puncture site for large green turtles (N = 150; body weight 100–155 kg; curved carapace length 110–115 cm). Previous measurements, based on >10,000 green turtles (1980–2000) from the same area for curved carapace length (100–115 cm; Omani Government records, the Ministry of Regional Municipalities and Environment), were in close agreement with our measurements.

Many procedures have been described for blood collection in turtles. Stephens and Creekmore (1983) described a procedure for cardiac puncture in freshwater turtles but this procedure is risky in the sea turtles because of their large size. Even in small turtles, it is a difficult and risky (Dessauer 1970; Gandal 1958). In addition, cardiac puncture can cause pericardial contamination (Frair 1977). The most popular and most successful procedure of venous blood collection from the lateral cervical sinuses (Owens and Ruiz 1980).

Some logistical problems in the use of cervical sinus.—Problems were not encountered when blood was collected from moderate-sized hawksbill, olive ridley, loggerhead, and green turtles (≤100 kg). However, in large green turtles (>100 kg) we faced logistical problems in obtaining blood from the dorsal cervical sinuses. Stretching the neck through a slit of a tilted platform or on the ground as suggested by Owens and Ruiz (1980) was difficult as these large turtles have powerful retracted neck muscles and are hard to stabilize on the platform or the sand. In most cases, one person encountered extreme difficulties in pulling the neck forward and keeping it in a stretched and tilted position. In addition, each of the front flippers must be held by one person, while a fourth person held the turtle in a stable position for the fifth person to perform the sampling.

After several attempts, we abandoned use of the platform because it was impractical to lift a large turtle onto the platform. Transferring the platform from one location to another was also difficult and time-consuming. Most importantly, the platform method caused the head to tilt downward, below the plastron level. Frequently, it was very difficult to keep the neck extended in this position long enough to collect a blood sample. Furthermore, the turtle struggled to move forward to retract its head. The turtle cannot be subjected to conditions interfering with its breathing movements, as the turtle quickly exhibits outward signs of disturbance and stress. When placed in a stressful condition, a significant change in plasma hormone levels from natural conditions is commonly observed in reptiles (Cree et al. 1990; Lance and Elsey 1986; Mahmoud and Licht 1997).

Procedure.—The following procedure, involving arterial blood sampling from the common carotid artery, can be useful in a variety of research projects. The sampling of arterial blood is preferred to venous blood because of the wider variability of parameters which might be investigated. The evaluation of arterial blood parameters can be studied under a specific set of physiological conditions, both *in vivo* and *in vitro*. Information about the status of parameters which can change rapidly in arterial plasma include pH, plasma lactate, total protein, urea, uric acids, and iron. Also, studies of mean corpuscular hemoglobin concentration, partial pressures of gases including Po_2 and Pco_2 and other hematological indices in arterial blood could be monitored.

We propose the following steps for a less stressful arterial blood sampling in large turtles (specifically green and loggerhead sea turtles) of different sizes (50–150 kg or larger), compared to cardiac or caudal punctures.

1. With a four-person team, turn the turtle on its back (ventral side up) and immediately have each front flipper restrained, one per person. A third person stretches the neck forward very gently. When the turtle in this position, the neck is easy to pull forward by one person because the retracted neck muscles lose their strength. The turtle also has limited mobility when placed ventral side up.

2. The fourth person will take the blood sample. Palpate the trachea and larynx along the mid-ventral line and insert a needle (1.5 inch–21 gauge) about 4.0–4.5 cm on either side of the lateral border of the trachea (Fig. 1). It is important to insert the needle lateral to the trachea by palpating the lateral outline of the trachea and the larynx to avoid injury to these organs. Adjust the depth of the needle between 2.0–3.0 cm with an angle of the needle entry perpendicular to the surface of the neck. Insert the needle into the common carotid artery about 7–10 cm from the angle of the jaws as the best source of blood collection. If this is not successful, try to insert the needle about 2–3 cm from the angle of the jaws, where the common carotid divides into the external and internal carotids

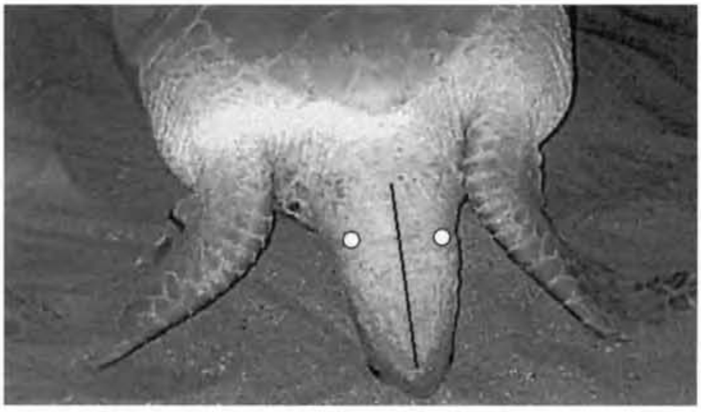

FIG. 1. Ventral aspect of the green turtle showing the mid-ventral view (line). The two circles on both sides of the neck represent the best points of entry into the carotid arteries.

(Hildebrand 1974, p. 292) or at other sites as long as a distance of 4.0–4.5 cm from the lateral outline of the trachea is maintained. Before the needle is inserted, retract the plunger slightly upward (about 0.5 cm) to make a slight air gap in the body of the syringe. This will allow for ease of blood flow entry into the syringe. The needle should be held in place when the blood starts to flow. At this point, move the plunger very slowly upward to maintain a continuous gentle suction until the required sample is obtained. If more than one sample is needed, vacutainer with evacuated blood collecting tubes should be used.

3. If there is a failure to draw blood within two minutes, the operation must stop immediately and the turtle must be allowed to withdraw its neck to its natural position so it can relax and breath normally. This procedure should not be repeated more than three times, as any blood collected in subsequent attempts could have distorted plasma constituent levels because of the onset of stress conditions. The turtle should be immediately released.

In summary, if the study requires arterial blood, our new method of blood collection is relatively unstressful and any volume of blood can be collected easily. If the study does not require arterial blood, the procedure of Owens and Ruiz (1980) using the cervical sinuses should be used, which is ideal for sea turtles under 100 kg. However, above this weight difficulties were encountered in the field. We suggest that if insufficient personnel are available in the field (four minimum), then the carotid method should be used as a less stressful procedure.

Acknowledgments.—This research was supported, in part, by grant number IG/SCI/BIOL/01/99, Deanship of Postgraduate Studies and Research, Sultan Qaboos University and by the Fulbright Program awarded to Prof. Ibrahim Younis Mahmoud, USA, and by the Directorate General of Wildlife and Nature Conservation, the Ministry of Regional Municipalities and Environment of the Sultanate of Oman. Effects of Placing Sticks in Pitfall Traps on Amphibian and Small Mammal Capture Rates

DUSTIN W. PERKINS
and
MALCOLM L. HUNTER, JR.

Pitfall traps associated with drift fences are a common method of capturing amphibians to determine relative abundance (Bury and Corn 1987; Corn 1994; Gibbons and Semlitsch 1982), but they also capture and kill small mammals as non-target species. When a study is being conducted at the same site over multiple years it is desirable to reduce mortality and leave the local faunal communities as undisturbed as possible to prevent confounding effects from sampling methodology. Pitfall traps can keep most amphibians alive if the cans are kept moist and checked frequently, and have not been found to decrease amphibian populations (Bury and Corn 1987; Corn 1994). However, pitfalls frequently result in the death of small mammals, and consequently can decimate small mammal populations (Bury and Corn 1987). This mortality could affect the results of the study, particularly when species (e. g. shrews) are predators of the target organisms. For ethical reasons animal use and care committees have sought to reduce mortality in ecological studies. Permitting agencies have also been reluctant to issue collection permits for researchers using pitfall traps because of high incidental mortalities of non-target species.

Karraker (2001) significantly reduced small mammal captures without a significant reduction in amphibian captures in pitfall traps by attaching jute twine to a coverboard over the pitfall trap. However, in some pitfall traps the twine was removed, or the end in the pitfall trap was eaten resulting in high small mammal mortality. Sticks have been placed in pitfall cans to reduce small mammal captures by giving them a ladder for escaping (S. Billig, L. Lichko, pers. comm.). It is possible that this ladder might also allow some amphibian species to escape. In addition, it is unlikely that small mammals will carry a stick the length of the pitfall trap away from the trap, and the stick method is less labor intensive than using jute twine. To our knowledge this practice and its effects on different species does not appear in the literature. We sought to measure the capture rates and subsequent mortality of amphibians and small mammals by placing sticks in the cans to allow small mammals to escape.

This study was done in conjunction with a larger project studying the effects of different riparian forest management practices on headwater streams. We conducted fieldwork in west-central Maine (latitude 45°25', longitude 70°35'). We sampled three streams in 2000 and eight streams in 2001. Nine streams were located in a mature second growth stand, and two streams had a 23 m buffer on either side of the stream with a clearcut adjacent to the buffer.

At each site we sampled the area from the stream bank out to 33 m with pitfall arrays. Each array consisted of two 3-m sections of fence with a pitfall placed at each end of the fence, for a total of

four pitfalls per array. We placed one fence in each array perpendicular to the stream and one fence parallel to the stream forming a t-configuration. There were four transects with three arrays per transect, resulting in 12 arrays and 48 pitfall traps per stream.

We constructed drift fences of partially opaque polyethylene supported by mason string, attached to hardwood stakes 40–50 cm high. We made pitfalls out of two #10 tin cans (36 cm each) taped end to end and we placed a funnel made from a plastic bowl in the top of the pitfall. Fencing went through the middle of the pitfalls to capture movement from both sides of the fence. We covered the bottom of each pitfall with 2–5 cm of water to keep amphibians from desiccating and force small mammals to swim, thus encouraging them to escape the pitfall. Traps were checked 2–3 times per week. Amphibians were identified and marked with a visible implant elastomer tagging method (Northwest Marine Technology, Shaw Island, Washington) (Davis and Ovaska 2001; Marold 2001; Nauwelaerts et al. 2000). We identified small mammals to species or genus and discarded them.

To evaluate the effect of sticks on amphibian and small mammal capture rates we placed sticks in selected cans. Sticks were obtained at each study site and were between 0.6 and 1.5 cm in diameter. One end of the stick was placed at the bottom of the can and the other end was approximately 5 cm above the top of the pitfall trap. In 2000, we removed sticks from two of the cans in each array from late June to early July for a total of 792 trap nights in both the stick and no stick treatment. In mid June 2001, we removed sticks from all cans within selected streams and compared them to streams with sticks remaining in all cans for a total of 1824 and 1488 trap nights in the stick and no stick treatment respectively.

Using a Wilcoxon rank-sum test, we found no significant year effects for any species or any treatment (Table 1), therefore we pooled data from 2000 and 2001 to increase sample size. We tested for differences between cans with sticks and cans without sticks with a Wilcoxon rank-sum test for each taxon.

We captured three species of amphibians totaling 181 individuals, and five species of small mammals totaling 466 individuals. We classified smoky shrews (*Sorex fumeus*), masked shrews (*S. cinereus*), and pygmy shrews (*Microsorex hoyi*) as shrews, and we classified white-footed mice (*Peromyscus leucopus*) and deer mice (*P. maniculatus*) as mice because of difficulties in identification of these species in the field.

We did not detect any significant differences between traps with sticks and traps without sticks for American toads (*Bufo americanus*), redback salamanders (*Plethodon cinereus*), or wood frogs (*Rana sylvatica*) (Table 2). Overall amphibian mortality was 8.6% and 9.7% in the cans with sticks and without sticks, respectively. We captured significantly more shrews, shorttail shrews (*Blarina brevicauda*), woodland jumping mice (*Zapus insignis*), mice, and southern red-backed voles (*Clethrionomys gapperi*) in traps without sticks than traps with sticks placed in them (Table 2). Capture rates of all small mammals combined were 14.5 times higher in pitfall traps without sticks than pitfall traps with sticks. Small mammal mortality was 100% for both years.

Our results show the placement of sticks in pitfall traps can dramatically reduce the number of small mammal captures and subsequent mortalities without affecting amphibian capture rates. The method is very inexpensive and requires very little extra labor. Future research involving the same study sites over multiple years should use sticks to reduce small mammal mortality and to reduce the potential effects that can result if an entire class of animals is eliminated in a study area.

We cannot rule out the possibility that our results from 2001 are a result of differences among study sites. However, we think this is unlikely because of the highly significant results, and the locations and habitats were similar for all sites. In addition, we continued to capture amphibians and small mammals at these streams through September 2001 with sticks placed in all pitfalls. Capture rates for small mammals were similar for streams that were previously in the stick or no stick treatment (D. Perkins, unpubl. data). We also did not test for differences among different sizes of sticks, and there is a potential that larger sticks than the ones used in this

TABLE 2. Results of Wilcoxon rank-sum test on the differences between traps with a stick and traps without a stick for amphibian and small mammal captures in June and July of 2000 and 2001 in western Maine.

Species	Stick #/100 TN	No Stick #/100 TN	S-Value	P
Amphibians				
American Toad	1.98	1.07	56.0	0.69
Redback Salamander	0.51	0.42	49.5	0.67
Wood Frog	1.52	1.80	59.0	0.56
Small Mammals				
Shorttail Shrew	0.29	1.76	34.0	0.01
Shrews[1]	0.51	11.62	28.0	<0.001
Mice[2]	0.08	1.11	28.0	<0.001
Redback Vole	0.29	1.49	34.0	0.02
Woodland Jumping Mouse	0.08	0.69	31.5	0.005

[2]Deer mice (*Peromyscus maniculatus*) and white-footed mice (*P. leucopus*).

study could allow some amphibians to escape.

After this study period was over we continued to capture amphibians throughout the summers of 2000 and 2001 with sticks in all cans. In subsequent sampling with sticks in all cans we caught the amphibians mentioned previously, as well as green frogs (*Rana clamitans*), blue-spotted salamanders (*Ambystoma laterale*), spotted salamanders (*A. maculatum*), two-lined salamanders (*Eurycea bislineata*), dusky salamanders (*Desmognathus fuscus*), spring salamanders (*Gyrinophilus porphyriticus*), and red-spotted newts (*Notophthalmus viridescens*). Although we do not have data for cans without sticks these individuals could not escape the cans with sticks in them. Placing sticks in the size range used in this study in pitfall traps made of two #10 tin cans can reduce small mammal capture, and does not seem to affect amphibian capture rates in forests in the northeastern United States.

Acknowledgments.—This study was supported by McIntire-Stennis funds, the National Fish and Wildlife Foundation, and the University of Maine Association of Graduate Students. We are grateful for the fieldwork done by K. Dillworth, Z. Sherry, and M. Sousa. Two anonymous reviewers provided valuable advice to improve this paper. The University of Maine Institutional Animal Care and Use Committee approved the methods used in this project. Plum Creek Timber Company, 7 Islands Land Management Company (Pingree Heirs), International Paper, and Mead Paper all provided access to their land.

Predation is the predominant source of nest mortality for most North American turtle species, including populations that are in decline (Brooks et al. 1992; Congdon et al. 2000). The identification of nest predators—crucial to understanding predator-prey relationships—has been previously accomplished largely by use of techniques that rely on the availability of physical evidence, such as animal sign (predominantly tracks) and nest/egg remains at depredated nests (e.g., Standing et al. 2000). Such techniques, however, are subjective and might preclude the identification of those species actually responsible for nest predation for numerous reasons, including: nesting substrates seldom retain identifiable tracks (Burger 1977; MacIvor et al. 1990), more than one species of predator might visit nests (Burger 1977; Larivière 1999; Leimgruber et al. 1994), and numerous predator species might leave similar nest remains (Hernandez et al. 1997a; Larivière 1999; Pietz and Granfors 2000). Further, the behavioral and temporal patterns of predators are rarely discernible via animal sign or nest remains. Therefore, comprehensive quantitative evaluations of turtle nest predation and predators have been infrequent (Burger 1977), although such detailed studies are clearly required (Tinkle et al. 1981).

The use of remote photography has allowed detailed evaluation of predation at artificial and natural avian nests (Maier and DeGraaf 2000; Pietz and Granfors 2000), yet there have been few applications of this technology in herpetofaunal studies (Cutler and Swann 1999). Preliminary efforts have indicated that remotely-triggered cameras might be used to study turtle nest predators (Doody and Georges 2000; Tuberville and Burke 1994); however, triggering devices (e.g., infrared beam) might be misaligned by animals, require frequent monitoring, and are often conspicuous (Hernandez et al. 1997b; Sadighi et al. 1995; see Fig. 2 in Doody and Georges 2000). Furthermore, such triggers often might be unduly activated by wind-blown vegetation, heavy precipitation, and by animals other than predators (Buler and Hamilton 2000; Rice et al. 1995; TJM, pers. observ.). To circumvent such limitations, we developed a small, simple, subterranean camera trigger that is relatively

FIG. 1. Raccoon (*Procyon lotor*) tripping subterranean camera trigger while excavating artificial turtle nest on 26 June 2000 at 0202 h in central Massachusetts.

easy to install, requires no maintenance, and is designed to activate only when the nest is excavated or otherwise greatly disturbed (Fig. 1).

Methods.—This trigger consists of a non-mercury tilt switch (manufactured by Assemtech Europe, part no. CW1300-1; distributed by Farnell Components [U.K.], part no. 540614; available from Newark Electronics® [USA]), 4.7 mm in diameter and 22.2 mm in total length, that contains two hermetically-sealed, non-toxic contact spheres (Fig. 2a). Each switch was soldered to the exposed doubled-leads at one end of a 4 m length of 24-gauge, solid telephone wire (Fig. 2b); with a modular plug crimped on the other end of the wire (Fig. 3). To re-insulate and waterproof the switch's soldered-connection, we dipped switch-ends of trigger wires in black Plastidip® (manufactured by PDI, Inc.; Circle Pines, Minnesota, USA), shaking off excess fluid and hanging them to dry. Plastidip® (previously used in field studies; e.g., Haskell 1999) provides a tough, flexible coating that has no apparent scent after being aired a few days. The modular plug of each trigger wire was connected to a modified 35-mm camera ("point-and-shoot" with 35-mm lens [f/3.5], ISO 200 color negative film [24 exp.], and a time-date function). The camera was enclosed in a camouflage-painted, weatherproofed wooden box with screened anti-condensation ports and glass windows (adapted from Danielson et al. 1996).

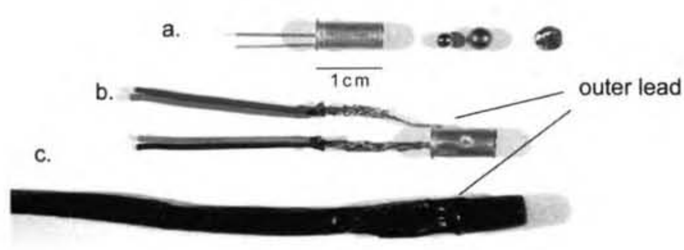

FIG 2. a) Non-mercury tilt switch showing contents, b) example of soldered switch, c) subterranean-end of trigger wire coated with black Plastidip®.

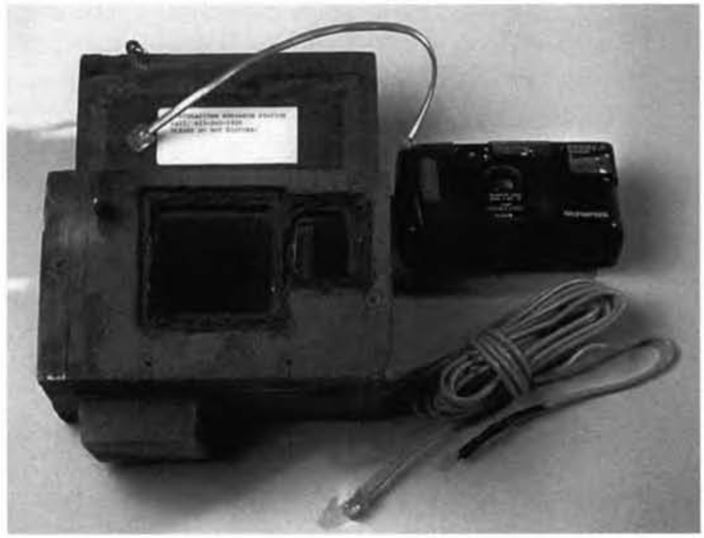

FIG. 3. Camera box assembly with trigger wire.

Switches cost \$2 each (all costs approximate U.S. dollars), a 4 m length of telephone wire costs \$1, a 429-ml can of Plastidip® costs \$8, the camera box with modifications costs \$15 to construct, a wood stake to support cameras set up in open areas costs \$1, and cameras with modifications cost \$105 (cost based on Danielson et al. 1996); totaling \$125 per assembly.

We tested triggers by monitoring a total of 111 artificial turtle nests with remotely-triggered cameras at known turtle-nesting habitats in southern New Hampshire and central Massachusetts during May–July 2000. Each nest contained several eggs of either snapping turtle (*Chelydra serpentina*) or northern bobwhite (*Colinus virginianus*). Camera triggers were positioned horizontally (similar to that illustrated in Fig. 2c) and buried 5–10 cm below the soil surface (within nest chambers) with moist soil repacked over the nest. Preliminary trials indicated that shallower trigger placement often resulted in their activation during heavy rain or when non-target animals, such as wild turkey (*Meleagris gallopavo*), stepped on nests. Trigger wires were buried in a thin slit between nest and camera at similar depth to triggers using a trenching shovel. Camera triggers were most sensitive to disturbance when the switches' outer lead (i.e., lead originating off switch casing [see Fig. 2b], easily seen under the Plastidip® coating [see Fig. 2c]) was placed downward. Cameras were mounted 1–1.5 m above ground on wooden stakes or trees at a distance of 1.5–2.5 m from nests (Fig. 4). While installing artificial nests and camera equipment, we wore clean gloves, clean rubber boots, and placed our equipment on clean plastic drop-sheets to minimize human scent and disturbance at the sites (Whelan et al. 1994).

Results and Discussion.—Our use of subterranean camera triggers enabled us to photograph several species of "turtle nest" predators without experiencing many of the problems associated with other triggering devices. Raccoons (*Procyon lotor*) were the most frequently photographed predators both in New Hampshire and Massachusetts. We also identified striped skunks (*Mephitis mephitis*) in Massachusetts, gray fox (*Urocyon cinereoargenteus*) in New Hampshire, and fishers (*Martes pennanti*) in New Hampshire as nest predators. To our knowledge, fishers have not previously been reported to depredate turtle nests. Red squirrels (*Tamiasciurus hudsonicus*) sporadically disturbed nests in New

Hampshire sufficiently to trigger cameras but did not destroy nests, suggesting either that they may be sensitive to our cameras' activity or that they are not turtle nest predators. Cameras also were occasionally triggered by moose (*Alces alces*) and white-tailed deer (*Odocoileus virginianus*) that stepped directly on turtle nests. Other apparent false-triggers (i.e., nothing visible in photograph) may have been caused by unidentified burrowing animals as posited by Congdon et al. (2000).

We also photographed multiple predators at the same nest in a number of cases, occasionally simultaneously. For example, a gray fox was photographed 4 June at 0150 h, just prior to a raccoon at 0201 h. At a second nest, a raccoon was photographed 9 July at 0442 h and 0609 h, followed by a fisher at 1806 h the same day. Additionally, we photographed multiple raccoons simultaneously at the same nests. Photographing subsequent visiting predators was possible after nests and camera triggers were either partially or completely excavated because our camera units remained active as long as unexposed film was available. Camera triggers proved extremely sensitive when uncovered, often repeatedly firing the camera at any slight disturbance such as raindrops or another predator. As used in our tests (i.e., without time-delays on cameras), trigger sensitivity also resulted in multiple exposures of individual predators engaged in prolonged digging activity, bouts often lasting at least 5 min. Such series of photographs occasionally provided useful behavioral insights; this, however, at the expense of photographs of any subsequent visitors when all film was exposed. Thus, even more nests may have had subsequent visitors than we were able to detect.

Further use of subterranean camera triggers, along with the time-date function of the cameras, may allow researchers to quantify patterns of turtle nest predation. For example, an association between precipitation events and predation on older nests has been reported (Congdon et al. 2000; Wilhoft et al. 1979); however, heavy precipitation has been reported to depress predation rates by inhibiting predators (Burger 1977; Hammer 1969; Legler 1954). Unfortunately, all reports have been incidental observations and the potential association has never been investigated systematically (Brooks et al. 1992). Confirmation of turtle nest predators and nest predation times, along with on-site precipitation-humidity data (and perhaps soil moisture gradients), would allow the quantitative evaluation necessary to establish not only the association between predation and precipitation but potentially underlying mechanisms as well.

FIG. 4. Field installation of camera and buried trigger at artificial turtle nest.

The presence of remote photography equipment (e.g., triggering mechanisms) may affect animal behavior (Cutler and Swann 1999; Maier et al., unpubl. data). As such, our inconspicuous subterranean triggers provide a more objective and effective means by which researchers may quantitatively examine turtle-nest predators and patterns of predation. Field trials yielded numerous detailed photographs of various potential predator species, their behavior, and time of activity while depredating artificial turtle nests. Additionally, multiple predator species were detected at the same nests, highlighting the shortcomings of subjective identification methods that rely on physical evidence such as animal sign or remains at depredated nests. These observations and others afforded by use of this inexpensive remote-recording device may prove useful in understanding many factors affecting the reproductive success of turtles.

Acknowledgments.—We thank M. Breen for field assistance; D. Small for assistance locating nesting sites; T. French and D. Pence for assistance collecting turtle eggs; the McIntire-Stennis Cooperative for financial support; L. Higgins, T. Fuller, and A. Whitlock for their comments on the manuscript; W. Zinni for access to nesting sites on private land; the Massachusetts Metropolitan District Commission, Division of Watershed Management, Quabbin section, for access to their management areas; and M. Sheremeta for proofing the manuscript.

In light of recent amphibian declines and local extirpations (Pechmann and Wake 1997; Stebbins and Cohen 1995), there has been renewed need to update and verify the continued persistence of local populations. Hovingh (1997) summarized biogeographical patterns and occurrences of amphibian species in the eastern Great Basin, USA. The extreme northeastern Great Basin is characterized by discrete valleys, which are remnant sub-basins of ancient Lake Bonneville. After surveying in 1987 and 1993, Hovingh (1997) was unable to verify continued presence of *Bufo woodhousii* and *B. cognatus* in some of these valleys and sub-basins. In this note, we report new records that augment and clarify Hovingh's (1997) results on the distribution of these two bufonids in the eastern Great Basin. We also present a new county record for *B. woodhousii* in southeastern Idaho, extending the reported range of this species.

Published range maps of *B. woodhousii* show a continuous distribution along the Wasatch Front and into southern Cache Valley, stopping at the Utah–Idaho state line (Stebbins 1985; Tanner 1931). Disjunct populations also occur along the Snake River Plain of Idaho and the Columbia River between Oregon and Washington (Nussbaum et al. 1983; Stebbins 1985). Hovingh (1997) stated that *B. woodhousii* does not occur in southeastern Idaho and failed to verify continued persistence of populations in Cache Valley (Fig. 1, Locality A) and the Blue Spring Sub-basin (in northern Utah; Fig. 1, Locality B) during field surveys in 1987 and 1993. He also questioned the validity of a record from upper Blacksmith Fork Canyon (which drains into Cache Valley; Fig. 1, Locality C), but did not give an opinion on the status of a record from Dry Lake, Cache Co. (BYU 542, Fig. 1, Locality D). Supplementing Hovingh's field surveys, our recent work in these areas produced the following records for *B. woodhousii*: USA (the following numbers correspond to locality numbers in Fig. 1): **UTAH:** CACHE CO.: (1) near Bear River, 5.1 mi (8.2 km) W of US Hwy 91 on Utah State Route 142, 1360 m elev. (41°55.10'N, 111°54.60'W). 14 July 1999. Paul C. Ustach and Daniel G. Mulcahy. UTA A-54480; (2) Cache Valley, Hwy 142, 0.9 mi (1.4 km) S of Clarkston, 1450 m elev. (41°54.39'N, 112°02.73'W). 29 July 1999. Daniel G. Mulcahy. UTA A-53937; (3) near Clarkston, Short Divide Rd., 1.0 mi (1.6 km) E of County line, 1490 m elev. (41°54.41'N, 112°04.22'W). 29 July 1999. Daniel G. Mulcahy. UTA A-53938; (4) Morton, 0.1 mi (0.2 km) S junction 1200 St/Center on 1200 St, 1360 m elev. (41°56.25'N, 111°56.62'W). 10 August 1999. Paul C. Ustach. UTA A-53939; (5) 1.4 mi (2.3 km) E junction 1200 St/Center on Center, 1360 m elev. (41°56.33'N, 111°54.98'W). 10 August 1999. Paul C. Ustach. UTA A-53940; BOX ELDER CO.: (6) Blue Spring Sub-basin, E Promontory Rd., 4.5 mi (7.2 km) S of 7200 N, 1295 m elev. (41°34.83'N, 112°29.39'W). 26 August 2000. Daniel G. Mulcahy and Becky L. Williams. UTA A-54640; (7) **IDAHO:** FRANKLIN CO.: Cache Valley, 3.6 mi (5.8 km) W of Franklin on 4800 S, 1380 m elev. (42°0.79'N, 111°52.54'W). 5 September 2001. Michelle R. Cummer. UTA A-54639.

Hovingh (1997) addressed only one record of *B. woodhousii* (UU 5484, Blacksmith Fork River, Cache Co., Utah), which he considered suspect due to elevation; however, Pack (1922a) reported an abundance of *B. woodhousii* in Benson (Cache Co.) after an outbreak of sugar-beet webworms. In addition to the specimens collected (see above), we observed other individuals of *B. woodhousii* at localities 4, 6, and 7 (Fig. 1) that were not collected. The individuals found in Cache Valley, Utah, were observed and collected over a period of two years (males were heard calling over a period of three years; PCU 1997–2000), and UTA A-53940 (Locality 4, Fig. 1) was a sub-adult collected amidst 10–15 conspecifics. Additionally, an individual *B. woodhousii* was observed at Locality 8 (Fig. 1; UTAH: BOX ELDER CO.: Blue Spring Sub-basin, E Promontory Rd., 9.2 km S of 7200 N, 1295 m elev. [41°34.01'N, 112°29.27'W]) and a chorus of males was heard at

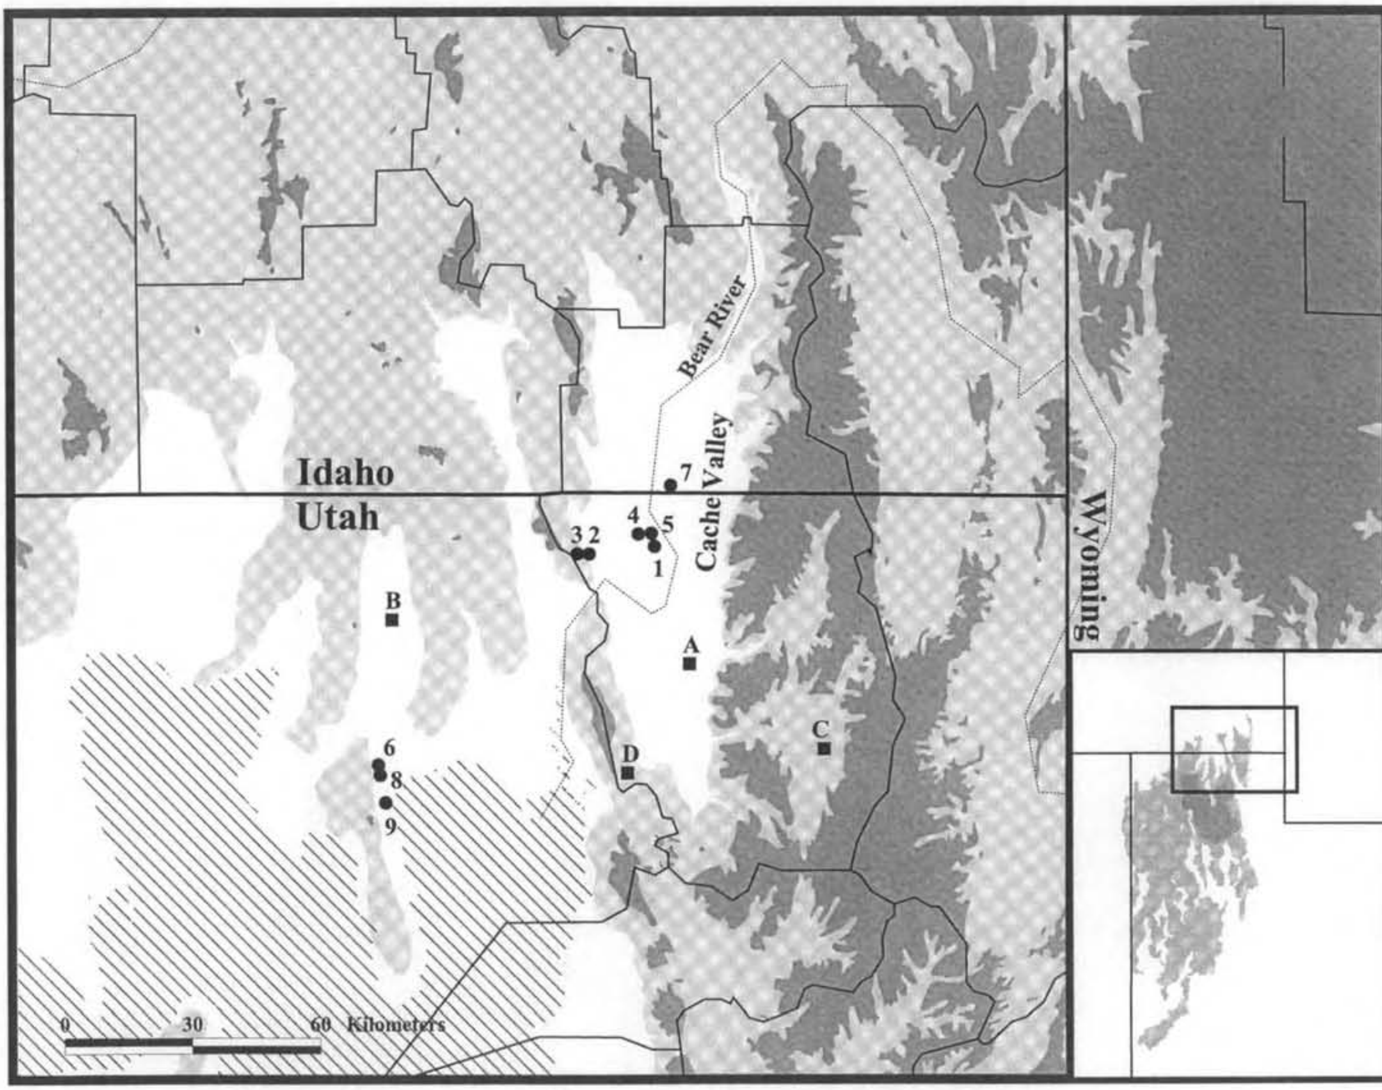

FIG. 1. Map showing the northeastern corner of Bonneville Basin, showing localities for *B. woodhousii* mentioned in the text. Squares represent records from the literature (records A and C were verified by us), and dots represent new locality records presented in this study. White area represents historical margins of Lake Bonneville at its greatest extent (modified from Currey et al. 1984). Crosshatched area represents current margins of the Great Salt Lake. Pale gray area represents elevations between 1525–2135 m, dark gray represents elevations above 2135 m. Thin lines represent county borders. Inset map indicates area enlarged and entire Bonneville Basin.

Locality 9 (Fig. 1; UTAH: BOX ELDER CO.: Blue Spring Sub-basin, E Promontory Rd., 12.9 km S of 7200 N, 1295 m elev. (41°32.05'N, 112°28.75'W) on 30 May 2002. Therefore, we believe viable populations of *B. woodhousii* still exist in these areas of the northeastern Bonneville Basin. The Utah records confirm the continued persistence of *B. woodhousii* in Cache Valley and the Blue Spring Sub-basin, while the Idaho record represents the northernmost record in Cache Valley and a new county record for Franklin Co., Idaho. Cache Valley is a continuous geographical feature that straddles the state line between Utah and Idaho. Based on this, we suspect that *B. woodhousii* occurs throughout Cache Valley and therefore further into Idaho than is represented by our observations.

The occurrence of *B. cognatus* in the eastern Great Basin has also received attention recently. A distribution map of *B. cognatus* presented by Krupa (1990) showed locality records from the eastern Bonneville Basin in the Salt Lake City, Bountiful, and Cache Valley areas and illustrated the range of the species to extend southward along the Wasatch Front through southwestern Utah (although no records are indicated in this latter region). Hovingh (1997) dismissed all records from the Great Basin as either being misidentified or introduced. Nevertheless, we are aware of museum records of *B. cognatus* from the eastern Great Basin of Utah and address these individual records for specific clarification. We have examined most of these specimens and verified their identifications. A specimen from Salt Lake City (TNHC 11593; 5 mi S on 14th S St, Salt Lake City) is an adult female *B. cognatus*. A specimen from Provo (USNM 13993) has been reidentified as *Spea intermontana* by the institution (S. Gotte, pers. comm.). A specimen from Payson (USNM 13995) is a juvenile *B. cognatus*. A specimen from Ogden (CU 10193) is unavailable for study at this time, so its identity remains uncertain. An additional specimen from SaltAir (UU 2855) is missing from that collection, therefore its identity also remains uncertain. Pack (1922b) reported two specimens of *B. cognatus* from Benson, Cache Valley. We have located one of these specimens (CAS 63924) and confirmed its identity as

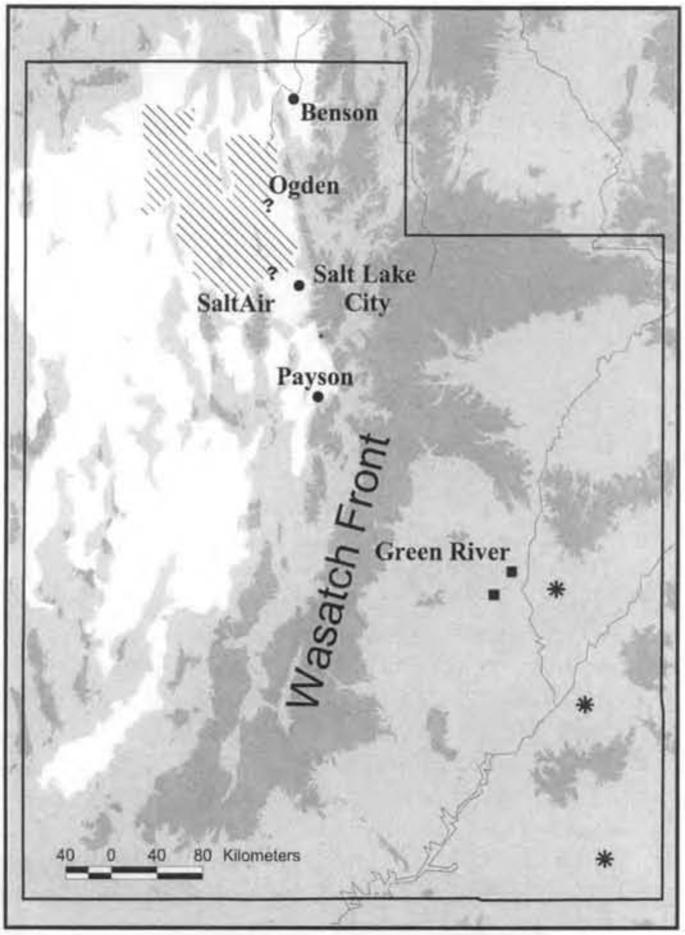

FIG. 2. Map showing the state of Utah, showing localities for *B. cognatus*. Dots represent verified, but suspect, voucher specimens (see text). Question marks represent museum specimens missing or unavailable for identification. Squares represent legitimate, verified records. Stars represent dot localities presented by Krupa (1990) for which we were unable to locate voucher specimens. White area represents historical margins of Lake Bonneville at its greatest extent (modified from Currey et al., 1984). Crosshatched area represents current margins of the Great Salt Lake. Pale gray area represents elevations between 1525–2135 m.; dark gray represents elevations above 2135 m.

a juvenile *B. cognatus*. We find it noteworthy that the largest collection of Utah amphibians (Monte L. Bean Museum, BYU) has no records of *B. cognatus* from the western Wasatch Front.

During our surveys in the field and of museum records, we have verified the identifications of only three voucher specimens of *B. cognatus* along the western Wasatch Front in the Great Basin (Fig. 2). The record from Salt Lake City (TNHC 11593) is suspect because the date of collection (23 June 1950; collected by Jameson) corresponds with the date of other specimens collected by the same individual in Texas (T. LaDuc, pers. comm.). The second record is from the town of Payson (USNM 13995), having been sent by Yarrow to USNM in 1884 (collection date unknown; S. Gotte, pers. comm.). A major human transportation route over the Wasatch Front exists between the towns of Green River and Payson. Because *B. cognatus* has been documented near the town of Green River on the Colorado Plateau (MVZ 29835; BYU 764; UMMZ 62155–60), the record from Payson could represent a rare dispersal event, human transport, or incorrect locality data. The Benson specimen (CAS 63924; only existing specimen of the two individuals reported by Pack 1922b) was found on a beet farm in 1921, and no others have been reported or collected in Cache Valley, Utah. We have verified the identification of this specimen (a subadult) and we have no *a priori* reason to doubt the authenticity of the locality record, but we do suspect that this represents a one-time human introduction event. Finally, we also note that the most recent of the three existing specimens was collected in 1950; we are not aware of any collected since that time. After considering these three geographically and temporally separated records, as well as the lack of any recent records of *B. cognatus* from this area, we do not believe that the natural range of this species extends north along the western side of the Wasatch Front.

We therefore confirm and detail the findings of Hovingh (1997) on *Bufo cognatus*. However, we were able to verify the continued persistence of *B. woodhousii* in the eastern Great Basin. Intense intermittent surveys can be augmented with continued surveillance of amphibians by qualified local observers and the deposition of voucher specimens in appropriate institutions. Recurrent records such as these can ameliorate problems in documenting amphibian declines, allowing a more thorough evaluation of this phenomenon.

Acknowledgments.—We thank the following institutions for specimen loans and record information: Jens Vindum (CAS), Travis LaDuc (TNHC), Steve Gotte (USNM), Jack Sites (BYU), Greg Schneider (UMMZ), and Eric Rickart (UU). Breck Bartholomew also provided useful information on *Bufo* records in Utah. Fieldwork in Utah was conducted under permit from Utah Division of Wildlife Resources issued to DGM. Finally, we thank the Herpetology Group at Utah State University for comments on this work.

Among amphibians, *Eleutherodactylus johnstonei* (Fig. 1) is rivaled in its propensity for range expansion only by the toad *Bufo marinus* (Kaiser 1997). However, whereas *B. marinus* made its biggest expansion jump, from South America to Australia, through purposeful human intervention and for a presumed agricultural benefit, *E. johnstonei* seems to move from one urban center to another continuously, at irregular intervals, both with and without the deliberate help of *Homo sapiens*. A compelling reason for carefully documenting the expansion of *E. johnstonei* is that it has been shown (Ovaska 1991; Pough et al. 1977; Stewart and Martin 1980) that its behavioral ecology and physiology allow it to colonize successfully where few other anurans can live, and that it may itself be a catalyst for the disappearance of other species (Hardy and Harris 1979). As a species with direct development, *E. johnstonei* does not require standing water for reproduction and is therefore all the more capable of settling into novel habitats. At this time, with reports of amphibian declines circling the globe, the example of this highly successful invader is instructive. We here detail the progress this species has made recently in South America, a region where dozens of native species have been impacted by human developments and the introduction of exotics, and where any additional environmental pressure on a delicately balanced frog fauna may become a tipping point (Gladwell 2000) for further declines of native frogs.

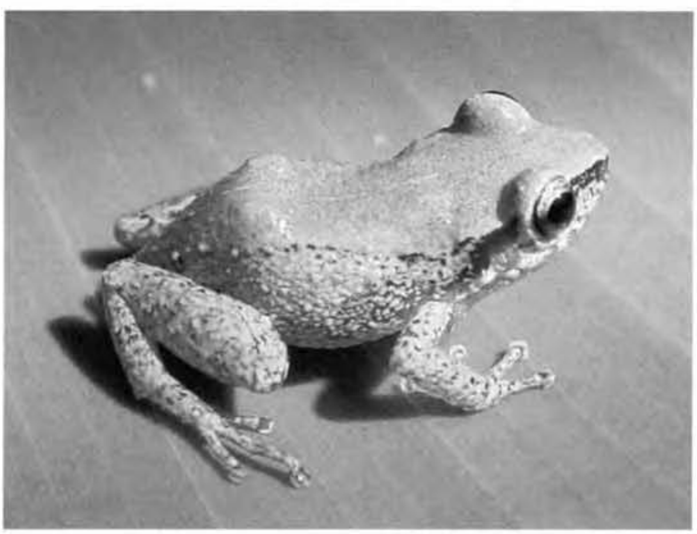

FIG. 1. *Eleutherodactylus johnstonei* from an empty lot in Irapa, Estado Sucre, Venezuela. This specimen is voucher LSUPC F-1388, a male of 27 mm snout–vent length that was photographed on 4 September 2001.

Eleutherodactylus johnstonei is a species endemic to the Lesser Antilles, though its exact island of origin has become obscured by centuries of presumably repeated human-mitigated introductions (Kaiser 1992, 1996). There have been many reports on the vectors by which these frogs move from one island to another, and conclusive evidence for both deliberate (e.g., Bequia—Lazell 1994; Bermuda—Pope 1917; Jamaica—Barbour 1910) and accidental (e.g. Dominica—Kaiser and Wagenseil 1995; Panama City—Ibáñez and Rand 1990; Trinidad—Kenny 1980) introductions is available. The first documented introduction into the South American mainland occurred prior to 1919 when a specimen was collected in Georgetown, British Guyana (Hardy and Harris 1979). This introduction was most likely accomplished by the same trade-related mechanism that carried the species throughout most of the other British dependencies in the Eastern Caribbean region (Kaiser 1992). A similar, trade-linked scenario was invoked by Lescure and Marty (1996) who encountered *E. johnstonei* in 1993 near the city center of Cayenne, the capital city of French Guiana. In surveys during the early 1970s (reported in Lescure 1981, 1983), Lescure had not heard the species in French Guiana. The most likely conduit for *E. johnstonei* into French Guiana is the trade in ornamental plants from Martinique (Lescure and Marty 1996).

An introduction of the species into Caracas, Venezuela, in the late 1950s (Juan Rivero, quoted in Hardy and Harris 1979), perhaps deliberately to introduce acoustic entertainment for a garden in the upscale suburb of Altamira, laid the foundation for its spread throughout that country and into neighboring Colombia, as detailed below. It is noteworthy that the species must have been highly restricted initially in its distribution in Caracas, as it is still absent from the thorough list published by Rivero (1961).

For verification of records, one would normally consider as confirmed only those localities for which voucher specimens or voucher photographs have been deposited in public institutions. However, in the case of "weed species," such as *Bufo marinus* or *E. johnstonei*, we realize that sightings verifiable through more than one source should also be considered. With species such as these, their presence may be duly noted by scientists yet no material might be collected because the species is so common and encountered all the time. Thus, after a species has become established at a locality for a certain period of time and becomes an integral part of that environment, voucher specimens are unlikely to be collected unless someone were interested in specifically documenting for science what has become common knowledge locally. In Venezuela, species for which this might be the case include *B. marinus*, *E. johnstonei*, *Leptodactylus fuscus*, *Hyla crepitans*, and *H. microcephala*. Our list of localities (Table 1) therefore includes a variety of places without voucher specimens. Institutional abbreviations used are as follows: CVULA—Colección de Vertebrados, Universidad de Los Andes, Mérida, Venezuela;

EBRG—Estación Biológica de Rancho Grande, Maracay, Venezuela; EDELCA—Departamento de Ecología, Corporación Venezolana de Guayana, Electrificación del Caroni C.A., Guri, Venezuela; ICN—Instituto de Ciencias Naturales, Museo de Historia Natural, Universidad Nacional de Colombia, Bogotá; LSUPC—La Sierra University Photographic Collection, Riverside, California; MNHN—Muséum National d'Histoire Naturelle, Paris, France; RMNH—Rijksmuseum van Natuurlijke Historie, Leiden, The Netherlands; SCN—Museo de Ciencias Naturales 'La Salle,' Caracas, Venezuela; UIS—Universidad Industrial de Santander, Bucaramanga, Colombia; ULABG—Universidad de Los Andes, Instituto de Geografía, Colección de Anfibios, Mérida, Venezuela; UVC—Universidad del Valle, Calí, Colombia; USNM—U.S. National Museum, Washington, D.C.

Expansion in Venezuela.—The Venezuelan capital of Caracas is a center for international trade and a crossroads for transportation across northern South America. Its shipping port and airport are both located along the coast just north of Caracas, in the cities of Catia La Mar, La Guaira, and Maiquetía. Among the most significant population centers in coastal northeastern Venezuela are Barcelona, Puerto La Cruz, and Cumaná. If a species is indeed transported both deliberately and accidentally, then these traffic centers would be logical places to find that species after an initial Caracas introduction.

Specimens of *E. johnstonei* from Caracas were deliberately released in Cumaná in 1967 (Hardy and Harris 1979), preempting a likely accidental introduction. By the mid-1970s, the species had spread throughout the city and along the coast near Cumaná (Hardy and Harris 1979). Its presence at Puerto La Cruz and for the coastal cities near Caracas was reported by Kaiser and Grismer (2001), though without vouchers.

Reports from local residents indicate that *E. johnstonei* has been in residence at Simón Bolívar International Airport for over a decade. Thus, the initial spread of the species from the site of introduction in Caracas occurred by both deliberate (Cumaná) and accidental (elsewhere) means. Additional records of the species' spread in Venezuela (Table 1) were published by Gorzula (1989), Kaiser and Grismer (2001), and La Marca (1992), and a cumulative listing appeared in Barrio-Amorós (1998). Yústiz (1977) mentioned the occurrence of an exotic *Eleutherodactylus*, possibly related to *E. portoricensis*, in his list of the frogs of the city of Barquisimeto that is clearly referable to *E. johnstonei*.

A specimen of *E. johnstonei* in the collections of the EBRG in Maracay that was collected on 01 June 1998 in Naguanagua, Carabobo State, a town close to Valencia on the far side of Lago Valencia from Maracay, represents the first specimen from that state. EBRG 3681 verifies the presence of *E. johnstonei* in the city of Maracay, Aragua State. The presence of *E. johnstonei* in Miranda State, the state surrounding the Distrito Federal in which Caracas is located, is ascertained by specimen EBRG 1756. This specimen is notable because it was collected at an altitude of 1300 m which we believe to be near the limit for the species (see below).

Reports of *E. johnstonei* from Bolivar State were made by Gorzula (1989). His list included Ciudad Bolívar, Ciudad Guayana, Upata, and Campamento Guri. Whereas museum vouchers are available for Guri (SCN 10919), the records for Ciudad Bolívar and Upata were based on the observation of calling males (Gorzula, in litt.). In listing the records for Ciudad Guayana, Gorzula (1989) used the name Ciudad Guayana as it is commonly used locally, encompassing two individual cities (Puerto Ordaz, San Félix). However, voucher specimens exist only for Puerto Ordaz town (e.g. RMNH 18488, EDELCA 5898), the western half of the Ciudad Guayana conglomerate separated from San Félix by the Caroni River.

Kaiser and Grismer (2001) reported *E. johnstonei* from Maturín and Caripe, cities in Venezuela's easternmost part. Unbeknownst to us, the species had been observed in Maturín a few years earlier and vouchered via photograph on the website of a hobby herpetologist (http://www.meos.ch/terra-typica/amphibia/amphibia.htm; Thomas Haag, pers. comm.). During their trip in the year 2000, Kaiser and Grismer also visited the city of Irapa, where *E. johnstonei* was not heard. During a visit in September 2001, we heard *E. johnstonei* in several localities in Irapa and conducted audio transects along all of the streets criss-crossing the downtown area (Fig. 2). It appears that the species was not present in large numbers where choruses were heard, and, at this time, its distribution throughout the city is discontinuous. Habitats for *E. johnstonei* in Irapa currently are gardens, empty lots, and construction sites, though it was still absent from the three parks in the downtown area during our survey. We also determined, through additional driving transects, that the species was not present during this period in either the downtown or surrounding areas of Güiria, the main port city on the Península de Paria, although this city is a logical next colonization locale for *E. johnstonei* after colonization of Irapa.

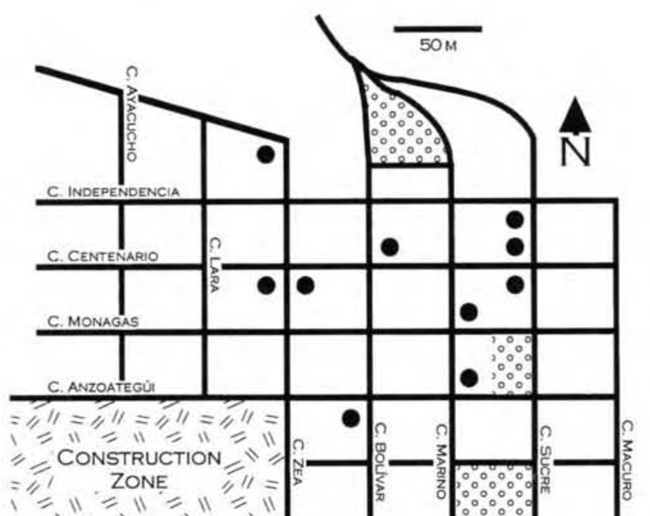

FIG. 2. Map of downtown Irapa, Estado Sucre, Venezuela. This map illustrates the distribution of *Eleutherodactylus johnstonei* in Irapa's downtown area shortly after its introduction between September 2000 and September 2001. In order to facilitate the description of localities, we considered the city's streets a grid, each of whose blocks represents four quarter squares. Filled circles indicate the quarter square in which audio transects revealed the presence of calling *E. johnstonei* males.

Expansion in Colombia.—Accounts of the invasion of *E. johnstonei* into Colombia (Table 1) have mostly been anecdotal (e.g. Kaiser 1997). Recent collecting has confirmed several localities, such as Bucaramanga (Ortega et al. 2002). Although reports supported by voucher specimens are few, the species is now also confirmed for Barranquilla and Cali (Table 1). It has apparently become established in Cartagena, but no voucher specimens are available.

The distribution of *E. johnstonei* across northern South America (Fig. 3) remains restricted to population centers. Within these locales, key habitats for *E. johnstonei* are private residences and areas where transportation of goods (such as construction materials, wood, or ornamental plants) is centered. It has been noted (Gorzula and Señaris 1998) that the occurrence of *E. johnstonei* in a residential area is generally an indicator of an elevated socioeconomic status of the residents, since the purchase of ornamental plants and the requirement of year-round watering requires considerable financial resources. This has earned the species the nickname "la rana burguesa" in some areas (Gorzula and Señaris 1998). This species has never been reported to cross from city habitats (e.g., parks, gardens, empty lots etc.), into native habitat. This is a key observation with respect to the species' competitive capacity and expansion pattern and may allay some fears about the potential impact of this species on local endemics. In Guyana, where *E. johnstonei* has existed for over 80 yrs, it has remained confined to the capital city of Georgetown, despite the proximity of agricultural land and disturbed forests, and the location of an international airport ca. 20 km to the south. Based on this pattern it is unlikely that there will be significant consequences for local endemics based on the mere presence of the species. However, if an endemic is negatively impacted by some form of human disturbance, such as short-term cutting of vegetation or residential construction in new forest tracts, *E. johnstonei* will likely move into that habitat before the native species has the opportunity to recover.

It is an interesting feature of *E. johnstonei* that its expansion seems to be limited by the availability of disturbed habitat. In collecting on all Eastern Caribbean islands with *E. johnstonei* populations, one of us (HK) found the species in seemingly undisturbed habitat in the southern Lesser Antilles only on the island of St. Lucia and in the northern part of that island chain on some of the Netherlands Antilles (Saba, St. Eustatius) and on the volcanic slopes of St. Kitts and Nevis. In all of these cases, *E. johnstonei*-populations in primary habitat exist in noticeably lower densities than populations in adjacent disturbed habitats. Although this is an anecdotal observation at this time, it allows us to hypothesize

*This population was listed as "*E. portoricensis* (= cooki)" by Yústiz (1977). We believe that Dr. Yústiz was trying to refer the observed individuals to a frog similar to the Puerto Rican coquí, now known as *E. coqui*. It is unlikely that he was trying to imply a synonymy of *E. portoricensis* and *E. cooki*, a distributionally highly restricted cave dweller.

FIG. 3. Map of northern South America (Colombia, Venezuela, Guyana), indicating locations for which *Eleutherodactylus johnstonei* has been confirmed.

that the capacity of *E. johnstonei* to expand into new habitats, and to survive at great densities, is optimized by habitat disturbance. The fact that all other populations of *E. johnstonei* are apparently linked to some abiotic disturbance (e.g., volcanism, degradation of native habitat by grazing and establishment of plantations, residential construction etc.) and exist at higher densities than in the forests of the islands mentioned above validates such an hypothesis. Assuming that any abiotic disturbance reduces, or at least temporarily rearranges, the complexity of a primary habitat, this might be what allows *E. johnstonei* to quickly move into ecological niches vacated temporarily or permanently by other species.

It is apparent that *E. johnstonei* is dispersed by a variety of means. Accidental introductions occur most likely through the ornamental plant trade, as evidenced by the species' appearance in upscale residential areas. With this vector, it is impossible to differentiate whether the species arrived through plants in one residence and was subsequently distributed by the owner of that residence to friends who enjoyed the frogs's vocalizations, or whether multiple plant introductions via plants occurred. In the suburbs of Caracas, Venezuela the species is now widely spread, and its escape from gardens of select barrios in other cities (such as Bucaramanga or Cali, Colombia) is only a matter of time. Purposeful introductions in South America are unequivocally documented only for Cumaná, Venezuela, and are apparently a simple matter of releasing a few *E. johnstonei* males and females in any area with disturbed vegetation.

One of the potential barriers to the spread of *E. johnstonei* is altitude. The population of *E. johnstonei* in Mérida occurs at the highest reported altitude for the species (up to 1400 m), followed by the populations in the town of La Parroquia near Mérida (ca. 1300 m) and near Caripe (ca. 1200 m). It seems that this altitude is the maximum possible for the species in this area of the Andes. At these altitudes, the species is tightly linked to gardens in south Mérida; no expansion from these localities has occurred at least over the last six years.

The pattern established by the spread of *E. johnstonei* in northern South America leads us to believe that the species will continue to expand its range by chance, and that there is no realistic possibility of stopping that expansion. If our current range map (Fig. 3) is considered a base map for the year 2001, predicted further points of introduction include all major cities in Colombia and Venezuela, as well as communities connected by trade and/or people movement south along the Andes into Ecuador, Peru, and Chile. It remains to be seen whether this species is capable of inhabiting higher altitude areas of the Andes (>3000 m), or disturbed sites in primary rainforests in the Orinoco and Amazon basins.

Acknowledgments.—We thank L. L. Grismer for critically reading the manuscript. In searching for additional records, the help of Gilson Rivas-Fuenmayor, Fernando Castro, Stefan Gorzula, Marinus Hoogmoed, Michel Breuil, Jean Lescure, and Martha Ramírez-Pinilla is gratefully acknowledged. This work was supported by grants from the College of Arts and Sciences and the University Research Council at La Sierra University.

The capture of crocodilians involves a certain amount of stress to both the animals and handlers. A variety of methods are currently employed to capture crocodilians. Specimens deemed too large to be captured safely by hand are typically noosed with ropes or catchpoles (Fowler 1995; Jones and Hayes-Odum 1994). Noosed specimens may thrash and twist about violently and/or roll in an attempt to free themselves, which risks injury to the individual, nearby crocodilians, and/or the handler (Fowler 1995). Minor injuries (e.g., abraded snouts, broken teeth) to display animals are aesthetically undesirable. Extensive physical exertion also leads to the accumulation of lactic acid in the blood, which can have negative and even fatal consequences in larger specimens (Seymour et al. 1987). The use of cylinders for trapping and/or restraining crocodilians has been previously described. Jones and Hayes-Odum (1994) used an open PVC pipe for securing large noosed Ameri-

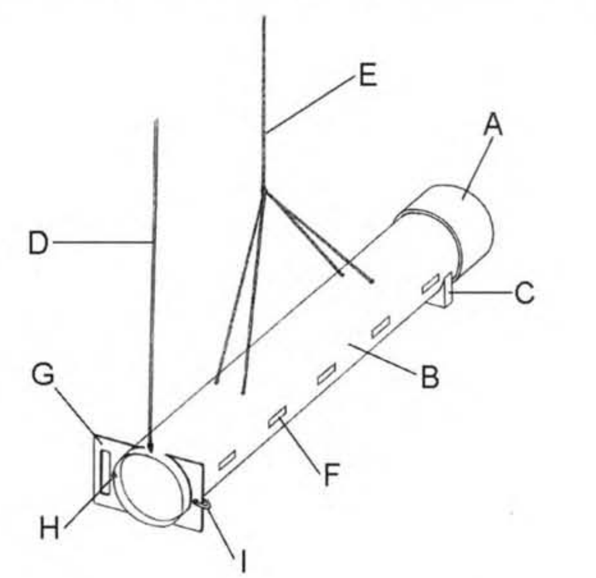

Fig. 1. Schematic diagram of the Crocodilian Capture Tube: (A) PVC cap; (B) PVC pipe; (C) stabilizer foot; (D) capture rope; (E) load bearing ropes; (F) drainage slits; (G) door; (H) door stopper bolt; (I) carabiner door latch.

can alligators (*Alligator mississippiensis*). This technique, however, still requires that the crocodilian be noosed with ropes, pulled into, and secured to the pipe. Wright (1999) advocated a similar approach, but with a corrugated metal sewer pipe. The objective of this paper is to describe a simple crocodilian capture method that provides an alternative to noosing in clear water pools possessing distinct corners and/or edges.

A piece of lime-green drainage pipe was used as the basis for our Crocodilian Capture Tube (Fig. 1). Although the effects of pipe coloration on trapping efficiency were not tested, it was felt that green was a more natural color than white. Pipe dimensions corresponded to the size of the crocodilians being captured. At Shark Reef, the tube is used to capture 5 year old captive bred *Crocodylus porosus* x *siamensis* with total body lengths ranging from 1.62 to 1.92 m and maximum abdominal diameters of 0.17–0.20 m. The pipe is 1.83 m in length, with a diameter of 0.36 m, thickness of 0.01 m, and mass of 34 kg (14-inch schedule 40 PVC pipe). As captive specimens are sometimes obese, pipe diameter should be carefully considered. A ratio of crocodilian girth to pipe diameter of $\geq$ 1:1.8 proved sufficient for our juvenile specimens. A commercially available white PVC cap (Fig. 1) was secured to one end of the pipe with PVC glue. A PVC stabilizing foot (Fig. 1), comprised of a U-shaped cradle, was then glued to the bottom of the pipe to ensure the trap would not roll once deployed on a relatively flat surface. This foot was affixed closest to the cap end of the pipe. This ensured that the entrance to the pipe would be almost flush with the bottom of the exhibit. Five holes were drilled into the top of the pipe in order to attach both capture and load-bearing ropes (Fig. 1). Drainage grooves were also cut along both sides of the pipe at intervals ranging from 0.15 to 0.35 m. In order to reduce stress to the captive animal, some water is allowed to remain in the pipe by cutting the grooves 0.13 m up from the bottom of the pipe. The remaining water, however, slowly seeps out from around the pipe's door. The entrance end of the pipe was modified to accommodate a sliding door (Fig. 1). The door is constructed as follows: A groove is cut around the end of the pipe, except for two 0.09 m sections on the top and bottom of the round pipe, in order to allow the insertion of a gray PVC door panel. Attached to the door is an imbedded stopper, comprised of a protruding stainless steel nut and bolt (Fig. 1).

A hole is drilled into the opposite end of the door that permits the clipping of an aluminum mountaineer's carabiner for a secure, tight-fitting, door that cannot be pushed out by the captive crocodilian's tail (Fig. 1). As a wet PVC door has the potential to be difficult to hold and maneuver quickly, the door also has a large integrated handle (Fig. 1). The total cost for the in-house manufacture of the Crocodilian Capture Tube with all new components is < US$ 400 at the time of writing. The most expensive component was the PVC cap at US$ 212. A new 6 m length of PVC pipe costs US$ 170. Such an expense is justifiable because of the safety afforded to the staff and the crocodilians.

The Crocodilian Capture Tube is used as follows: The tube is submerged to the bottom of an exhibit pool and up against an edge (Fig. 2A). Pool edges help to guide the crocodilian into the mouth of the tube. The trap is then left in place without further disturbance for ± 15 minutes, thus allowing crocodilians the opportunity to settle onto the bottom of the tank. The target crocodilian is then gently nudged with a smooth ended pole in the direction of

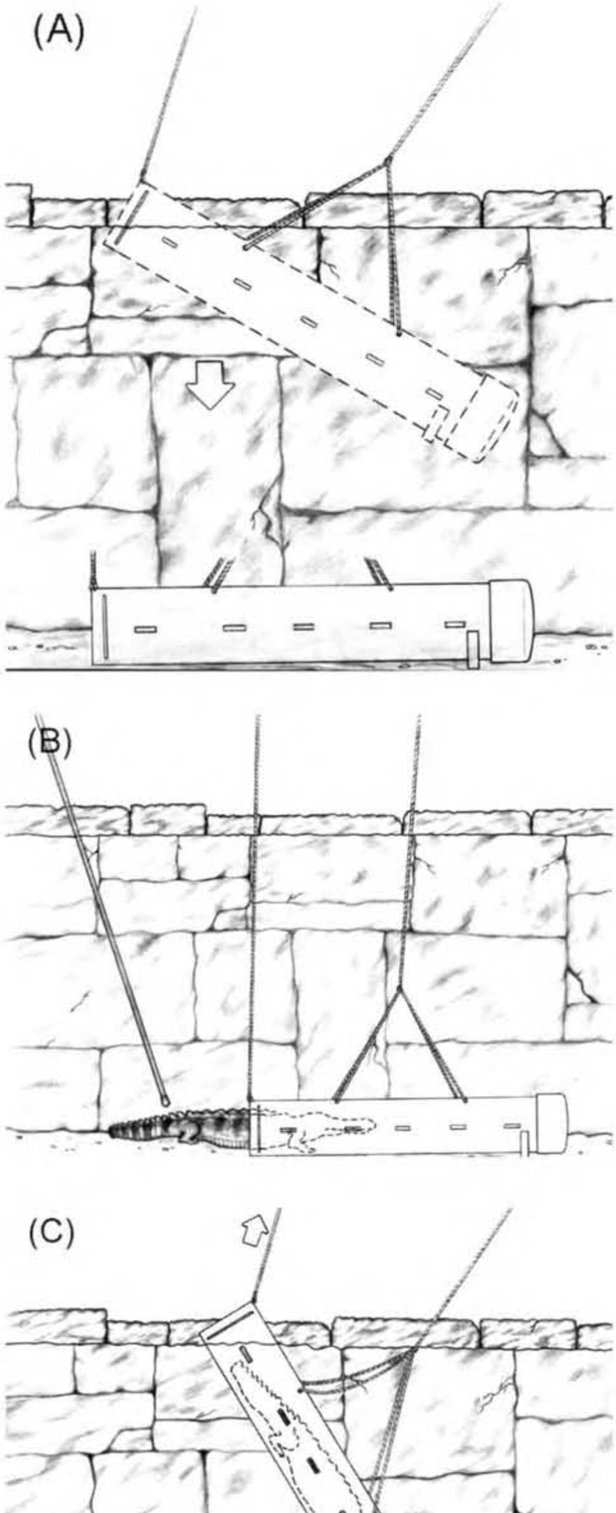

FIG. 2. Deployment and use of the Crocodilian Capture Tube from the edge of a deep concrete exhibit pool with clear water: (A) positioning tube at bottom of exhibit along an edge; (B) prodding crocodilian into the tube; (C) quickly retrieving entrance end of pipe by pulling up on the capture rope.

the tube entrance (Fig. 2B). To elicit movement in the desired direction, prodding is best directed towards a crocodile's posterior (e.g., base of tail, thigh) (pers. obs.). Our crocodilians bite at poles that approach or come in contact with their heads, rather than move in the desired direction. Juvenile *Crocodylus porosus* x *siamensis* entered the pipe readily, and most captures were accomplished in < 5 minutes. Once a crocodilian enters the pipe, the entrance side is quickly pulled up and out of the water by means of an attached capture rope (Fig. 2C). The crocodile is thus momentarily in an inverted vertical position and is unable to back out of the smooth, water-filled, pipe. The entrance is quickly sealed with the sliding door and secured. Finally, the pipe is pulled completely out of the water by means of the second load bearing rope handle (Fig. 1; Fig. 2C). Drainage slits allow water to quickly drain from the pipe (Fig. 1). The crocodile is then safely contained in a dark, wet, and smooth pipe. We believe that these characteristics provide a relatively non-stressful environment for the animal and prevent physical injury. A minimum of two people are required to trap a juvenile crocodilian in this fashion, although more may be required to lift and transport the pipe and its occupant. At Shark Reef, the entire process takes place with staff standing along the edge of an eight-foot deep exhibit pool. Although this technique reduces stress during capture and transport, confined crocodilians should not be exposed to excessively warm areas and/or direct sunlight, as thermal stress can also be fatal. To release a crocodilian, the pipe entrance is simply oriented towards a body of water and the door is removed. Tilting the pipe causes the crocodilian to slide out tail first into the water.

The Crocodilian Capture Tube has many advantages over current capture methodologies: (1) No direct physical contact is required between the crocodilian and handlers; (2) there is no need for securing the crocodilians jaws; (3) specimens can be captured underwater with ease; (4) no stressful thrashing or rolling behavior is exhibited by captured crocodilians; (5) there is no longer a need to cover a crocodilian's eyes, as it is in a dark tube; (6) the device serves as a safe short-term holding and on-site transport container; (7) no sedatives are required to capture and/or transport an animal; and (8) the crocodilians body is evenly supported during transport.

Acknowledgments.–We thank Adam Britton, Andy Odum, and one anonymous reviewer for helpful comments on earlier drafts of this manuscript. We would also like to thank Michael Eaton for the splendid illustrations. Finally, we acknowledge Christopher Blanar for his help in obtaining an elusive reference.

NATURAL HISTORY NOTES

Instructions for contributors to Natural History Notes appear in Volume 33, Number 1 (March 2002). However, please take note of the updated information below.

Current section editors: **Marc P. Hayes** (amphisbaenids, crocodilians, lizards, and *Sphenodon*; mhayesrana@aol.com); **Charles W. Painter** (amphibians; cpainter@state.nm.us); **Gordon W. Schuett** (snakes; gschuett@asu.edu); and **James Harding** (turtles; hardingj@pilot.msu.edu). Electronic submission of manuscripts is required (as Microsoft Word or Rich Text format [rtf] files, as e-mail attachments). Authors without the ability to send manuscripts electronically may supply hard copy instead. Figures can be submitted electronically as JPG files, although higher resolution TIFF or BMP files will be requested for publication. If figures cannot be provided in this format, you may send them to the section editor for scanning. Additional information concerning preparation and submission of graphics files is available on the SSAR web site at: http://www.ukans.edu/~ssar/HRinfo.html.

CAUDATA

AMPHIUMA MEANS **(Two-toed Amphiuma). OVERLAND MIGRATION.** *Amphiuma means* is a large aquatic salamander with reduced limbs and an eel-like appearance. Amphiumas inhabit relatively shallow, lentic water habitats and water levels in these habitats often fluctuate seasonally and/or annually. During periods of drought, amphiumas are known to aestivate in burrows within organic sediment of dry lake bottoms (Knepton 1954. Copeia 1954:68; Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing Co., Auburn, Alabama). There are no published accounts of *A. means* traveling overland, although the possibility of overland migration/dispersal has been suggested (Snodgrass et al. 1999. Copeia 1999:107–113). Here, I report overland migration of an adult amphiuma from a drying lake during a drought.

Lake Jackson in Leon County, Florida, USA is a 1620 ha sinkhole lake that dried to 10% of normal surface area in 1999–2000 during a prolonged drought in northern Florida. In order to monitor the mass migration of reptiles and amphibians from the drying lake, I constructed an 853-m drift fence along U.S. Highway 27N adjacent to the northwest part of Lake Jackson. Animals were migrating to a 7-ha lake (Little Lake Jackson) that did not dry located immediately to the west of U.S. 27. On 10 June 2000 at 1100 h, I found a dead, partially desiccated adult male *A. means* (SVL 40 cm, TL 79 cm) at the drift fence. The body was positioned perpendicular to the fence with the snout touching the fence. The amphiuma apparently moved during the previous night as it was not observed at the fence at 2030 h on 9 June. There were no signs of injury that might suggest it was carried there by a predator. There were clear skies 9–10 June and full sunshine on the morning of 10 June; the only moisture was morning dew on dense vegetation.

There are two possible scenarios to describe the terrestrial movement of this amphiuma: either it migrated from a drying lake pool or it emerged from an aestivation burrow. The latter is unlikely as there was no rainfall since 5 June 2000 (0.05 cm) and, therefore, probably no trigger mechanism that might stimulate emergence from aestivation in an area of lake bottom that was dry for 1–2 years and covered with terrestrial vegetation. Although most amphiumas probably aestivate under organic sediment in the littoral zone of drying lakes (Aresco 2001. Herpetol. Rev. 32:32–33), some individuals may remain active in slowly receding water with little or no aquatic vegetation. Under these conditions, the increased
